For any larger load use carbon-alloy steel tubing rated for high strength. A moderate antenna installation in an 80 MPH wind might exert 40,000 to 50,000 pounds per square inch (psi) on the mast. Pipe has a yield strength of about 35,000 psi, so you can see that pipe is not adequately rated for this type of use. Chrome-moly steel tubing is available with yield strengths from 40,000 psi up to 115,000 psi but it is expensive. **Table 28.3** shows the

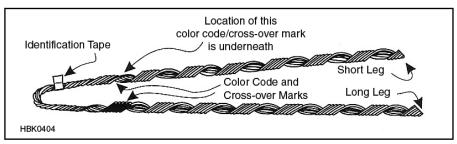

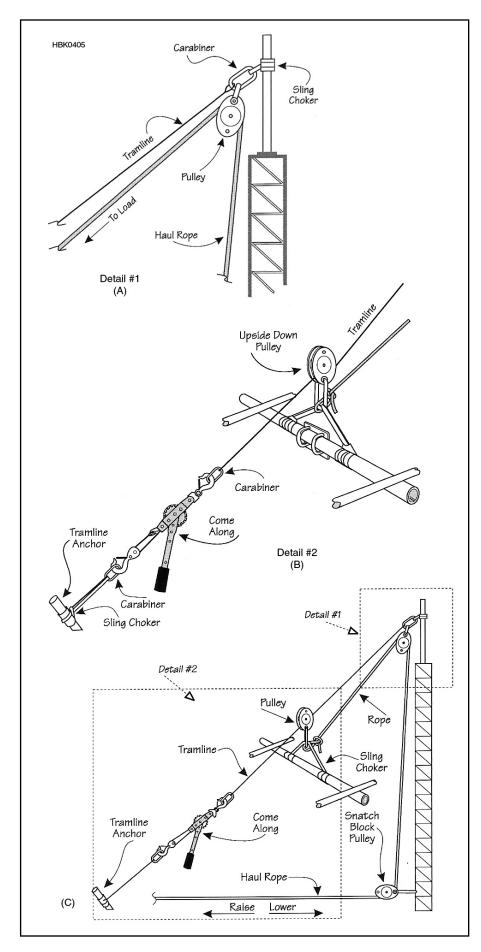

Figure 28.16 — A PreFormed Line Products Big Grip for guy wires.

ratings of several materials used as masts for amateur radio antennas.

Calculating the required mast strength can be done by using a software program such as the *Mast*, *Antenna and Rotator Calculator* (*MARC*) software. (See the References.) The software requires as inputs the local wind speed, antenna wind load, and placement on the mast. The software then calculates the mast bending moment and will recommend a suitable mast material.

28.2.5 Weatherproofing Cable and Connectors

The biggest mistake amateurs make with coaxial cable is improper weatherproofing. (Coax selection is covered in the chapter on **Transmission Lines**.) **Figure 28.18** shows how to do it properly. First, use high-quality electrical tape, such as 3M Scotch 33+ or Scotch 88 (same as 33+ but 1.5 mil thicker). Avoid inexpensive utility tape. Before weatherproofing, tighten the connector (use pliers carefully to seat threaded connectors — hand-tight isn't good enough).

When you're done making a tape wrap, sever the tape with a knife or tear it very carefully — *do not* stretch the tape until it breaks. This invariably leads to "flagging" in which the end of the tape loosens and blows around in the wind. Let the tape relax before applying the next layer.

Begin by applying two wraps of electrical tape around the joint. Next put a layer of butyl rubber vapor wrap over the joint. (3M Butyl Mastic Tape 2212 is one such material. Butyl rubber tape is usually available in the electrical section of hardware and home improvement stores.) Finally, add two more layers of regular tape over the vapor wrap, creating a professional-quality joint that will never leak. Finally, if the coax is vertical, be sure to wrap the final layer so that the tape is going up the cable as shown in Figure 28.18. In that way, the layers will act like roofing shingles, shedding water off the connection. Wrapping it top to bottom will guide water between the layers of tape.

An alternative method suggested by K4ZA begins with a wrap of "military grade" Teflon tape — a thread wrapping tape thicker than what you'll find at your local hardware store. (McMaster-Carr#6802K44) Over that,

Figure 28.17 — At A, rigging the top of the tower for tramming antennas. Note the use of a sling and carabiner. (B) Rigging the anchor of the tramline. A come-along is used to tension the tramline. (C) The tram system for getting antennas up and down. Run the antenna part way up the tramline for testing before installation. It just takes a couple of minutes to run an antenna up or down once the tramline is rigged.

install a layer of Scotch 130C (liner-less rubber sealing tape), using a 50% wrap (half the tape width is overlapped). Cover that with a layer of either Scotch 33+ or Scotch 88. Taken apart, 20-year-old joints have revealed connectors with like new appearance.

28.2.6 Climbing Safety

Tower climbing is a potentially dangerous activity, so you'll need to use the proper safety equipment and techniques. OSHA, the Federal Occupational Safety and Health Administration, publishes rules for workplace safety.

Although amateurs are not bound by those rules, you'll be much better off by following them. What equipment and techniques you use are up to you. As long as you've got the right safety equipment and follow the basic safety rules you won't have any problems.

SAFETY AWARENESS AND PREPARATION

One of the most important aspects of safety is having the knowledge and awareness to do a job safely and efficiently. You must have the mental ability to climb and work at altitude while constantly rethinking all connections, techniques and safety factors. Safely climbing and working on towers is 90% mental. Mental preparedness is something that must be learned. This is an occasion where there is no substitute for experience. The biggest obstacle for anyone is making the mental adjustment. Properly installed towers are inherently safe and accidents are relatively rare.

You should also check your safety equipment every time before you use it. Inspect it for any nicks or cuts to your belt and safety strap. Professional tower workers are required to check their safety equipment every day and you should check yours before each use.

One of the most important lessons for tower climbing is that you have four points of attachment and security—two hands and two feet. When climbing, move only one point at a time. That leaves you with three points of contact and a wide margin of safety if you ever need it. This is in addition to having your fall-arrest lanyard (see below) connected at all times

Another recommended technique is to always do everything the same way every time. That is, always wear your positioning lanyard on the same D-ring and always connect it in the same way. Always look at your belt D-ring while clipping in with your safety strap. This way you'll always confirm that you're securely belted in. Always look!

PERSONAL SAFETY EQUIPMENT

The most important pieces of safety equipment are the *personal fall arrest system* (PFAS) you wear and the accompanying lanyards that attach to it (**Figure 28.19**). The PFAS has leg loops and suspenders to help spread the fall forces over more of your body and has the ability to hold you in a natural position with your arms and legs hanging below you where you're able to breathe normally.

Two or more lanyards are used. One is the positioning lanyard (**Figure 28.20**). That is, it holds you in working position and attaches to the D-rings at your waist. They can be adjustable or fixed and are made from different materials such as nylon rope, steel chain or special synthetic materials. An adjustable positioning lanyard will adjust to almost

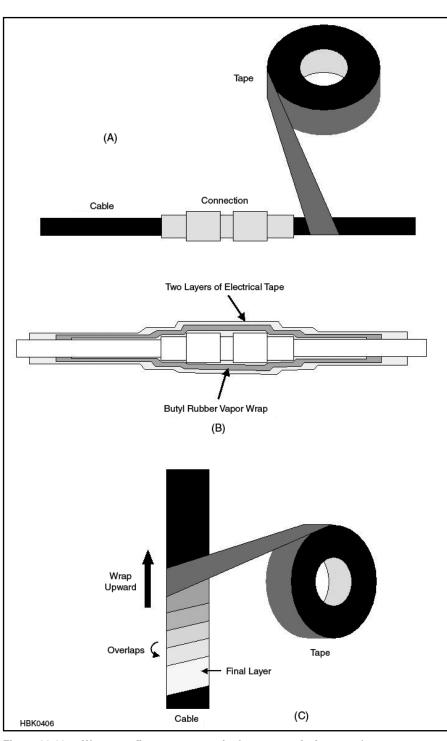

Figure 28.18 — Waterproofing a connector in three steps. At A, cover the connectors with a layer of good-quality electrical tape. B shows a layer of butyl rubber vapor wrap between the two layers of electrical tape. C shows how to wrap tape on a vertical cable so that the tape sheds water away from the connection. (Drawing (C) reprinted courtesy of *Circuitbuilding for Dummies*, Wiley Press)

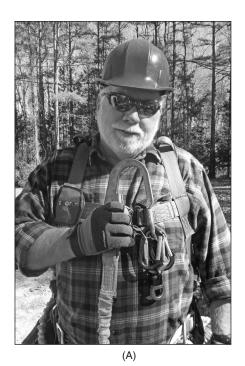

Figure 28.19 —The well-dressed tower climber with a climbing or "gorilla" hook (A). Note the waist D-rings at (B) for attaching the positioning lanyard as well as the suspenders and leg loops. The climber also has working boots, gloves, safety glasses, and hardhat. [Don Daso, K4ZA, photos]

(B)

any situation whereas a fixed-length one is typically either too long or too short. A rope lanyard is the least expensive.

Leather safety equipment was outlawed some years ago by OSHA so don't use it. This includes the old-fashioned safety belt that utility pole linemen used for years but offers no fall arrest capability. If you drop down while wearing a safety belt, your body weight can cause it to rise up from your waist to your ribcage where it will immobilize your diaphragm and suffocate you. On the other hand, you can use a safety belt for positioning when it's worn over an FAH. Just don't depend on it to catch you in case of a fall.

The other lanyard is the fall arrest lanyard, shown in **Figure 28.21**, which attaches to a D-ring between your shoulder blades. The other end attaches to the tower above the work position and catches you in case of a fall. The simplest is a 6 foot rope lanyard which is inexpensive but doesn't offer any shock absorption. There are also shock absorbing varieties that typically have bar-tacked stitches that pull apart under force to decelerate you. *DO NOT* cut corners on buying or using safety equipment; you bet your life on it every time you use it!

Figure 28.21 — The fall-arrest lanyard is above the climber so that the climber can climb up to it. The fall-arrest and positioning lanyards are then "leapfrogged" so that the climber remains attached to the tower 100 percent of the time. [Steve Morris, K7LXC, photo]

OSHA rules and good common sense say you should be attached to the tower 100% of the time. You can do this several ways. One is to attach the fall arrest lanyard above you and climb up to it. Use your positioning lanyard to hold you while you detach it and move it up again. Repeat as necessary. Another option is to use a pair of fall arrest lanyards, attaching one then the other as you climb the tower. This typically means using one with your left hand then the second with your right hand. The attachment point on the tower should be capable of sustaining a 3000-pound load.

Boots should be leather with a steel or fiberglass shank. Diagonal bracing on Rohn 25G is only 5/16 inch rod — spending all day standing on that small step will take a toll on your feet. The stiff shank will support your weight and protect your feet; tennis shoes will not. Leather boots are mandatory on towers like Rohn BX that have sharp X-cross braces. Your feet are always on a slant and that is hard on feet.

A hard hat and safety goggles is highly recommended. Just make sure they are ANSI or OSHA approved and that you and your crew wear them. As you'll be looking up and down a lot, a chin strap is essential to keep the hard hat from falling off.

If you do a lot of tower work, your hands will take a beating. Gloves are essential keep several spare pair for ground crew members who show up without them. Cotton gloves are fine for gardening but not for tower work; they don't provide enough friction for climbing or working with a haul rope. Leather gloves are the only kind to use; either full leather or leather-palmed are fine. The softer the gloves the more useful they'll be. Stiff leather construction gloves are fine for the ground crew but pigskin and other soft leathers are better for the climber because you can thread a nut or do just about any other delicate job with these gloves on. K4ZA recommends what are called "framer's gloves," which are leather gloves with the thumb and two index finger-tips removed. This provides heavy-duty protection for the palm and backs of the hands, but allows fine

finger-tip control for delicate work.

SAFETY TIPS

- 1) Don't climb with anything in your hands; attach it to your safety belt if you must climb with it or have your ground crew send it up to you in a bucket.
- 2) Don't put any hardware in your mouth; it can easily be swallowed.
- 3) Remove any rings and/or neck chains; they can get hooked on things. Long hair should be secured.
- 4) Be on the lookout for bees, wasps, hornets, and their nests. If you do run into a stinging insect, use Adolph's Meat Tenderizer on the sting it contains the enzyme papain which neutralizes the venom. Have a small jar in your tool kit.
- 5) Don't climb when tired; that's when most accidents occur.
- 6) Don't try to lift anything by yourself; one person on a tower has very little leverage or strength. Let the ground crew use their strength; save yours for when you really need it
- 7) If a procedure doesn't work, assess the situation and re-rig, if necessary, before trying again.

GROUND CREW SAFETY

The climber on the tower is the boss. Before tower work starts, have a safety meeting with the ground crew. This "tailgate" meeting is important to get everyone on the same page, work-wise, detailing the work to be done and how to do it. This also the time and place to introduce the ground crew to gear or hardware they may be unfamiliar with such as a capstan winch, carabiners, rock climbing gear, special tools, and so on.

Explain what is going to be done and how to do it as well as introducing them to any piece of hardware with which they may not be familiar (for example, carabiners, slings or come-along winches).

As part of the ground crew, there are a few rules to follow:

- 1) The climber on the tower is in charge.
- 2) Don't do anything unless directed by the

climber in charge on the tower. This includes handling ropes, tidying up, moving hardware, and so on.

- 3) If not using radios to communicate, when talking to the climber on the tower, look up and talk directly to him or her in a loud voice. The ambient noise level is higher up on the tower because of traffic, wind and nearby equipment.
- 4) Communicate with the climber on the tower. Let him or her know when you're ready or if you're standing by or if there is a delay. Advise the climber when lunch is ready!

28.3 RF Safety

Amateur Radio is basically a safe activity. In recent years, however, there has been considerable discussion and concern about the possible hazards of electromagnetic fields (EMF), including both RF energy and power frequency (50-60 Hz) EMF. FCC regulations set limits on the maximum permissible exposure (MPE) allowed from the operation of radio transmitters. Following these regulations, along with the use of good RF practices, will make your station as safe as possible.

This section, written by the ARRL RF Safety Committee (see sidebar), deals with the topic of electromagnetic safety.

28.3.1 How EMF Affects Mammalian Tissue

All life on Earth has adapted to live in an environment of weak, natural, low frequency electromagnetic fields, in addition to the Earth's static geomagnetic field. Natural low-frequency EM fields come from two main sources: the sun and thunderstorm activity. During the past 100 years, manmade fields at much higher intensities and with different spectral distributions have altered our EM background. Researchers continue to look at the effects of RF exposure over a wide range of frequencies and levels.

Both RF and power frequency fields are classified as *nonionizing radiation* because

the frequency is too low for there to be enough photon energy to ionize atoms. *Ionizing radiation*, such as X-rays, gamma rays and some ultraviolet radiation, has enough energy to knock electrons loose from atoms. When this happens, positive and negative *ions* are formed. Still, at sufficiently high power densities, nonionizing EMF poses certain health hazards.

It has been known since the early days of radio that RF energy can cause injuries by heating body tissue. Anyone who has ever touched an improperly grounded radio chassis or energized antenna and received an RF

burn will agree that this type of injury can be quite painful. Excessive RF heating of the male reproductive organs can cause sterility by damaging sperm. Other health problems also can result from RF heating. These heat related health hazards are called *thermal effects*. A microwave oven is an application that puts thermal effects to practical use.

There also have been observations of changes in physiological function in the presence of RF energy levels that are too low to cause heating. These functions generally return to normal when the field is removed. Although

research is ongoing, no harmful health consequences have been linked to these changes.

In addition to the ongoing research, much else has been done to address this issue. For example, FCC regulations set limits on exposure from radio transmitters. The Institute of Electrical and Electronics Engineers, the American National Standards Institute and the National Council for Radiation Protection and Measurement, among others, have recommended voluntary guidelines to limit human exposure to RF energy. The ARRL maintains an RF Safety Committee, consist-

The ARRL RF Safety Committee

Imagine you wake up one day and the newspaper headlines are screaming that scientists have discovered radio waves cause cancer. How would you react? How would your neighbor react? You may not have to imagine very hard because the news has been inundated with this type of story regularly over the past couple of decades. Clearly our society has not been decimated by epidemics of diseases since the vast increase in cellular telephone use. Some people deal with this discrepancy by ignoring all scientific reports. Others adopt a pessimistic attitude that technology is going to kill us all eventually, while still others treat every such story as "the truth" and militantly try to stop the transmission of RF energy. The reality is that while all scientific study is complex, the study of electromagnetic biological effects is even more so. Few newspaper reporters are capable of understanding the nuances of a scientific study and are even less able to properly report its results to the lay public. As a result many newspaper stories mislead the public into thinking that a scientific study has found something about which they need to be warned.

The ARRL has dealt with this dilemma by creating the RF Safety Committee, a group of experts in the facets of medical, scientific and engineering investigation needed to fully critique and understand the results of studies on electromagnetic biological effects. Experts in Dosimetry, Public Health, Epidemiology, Statistical Methods, General Medicine and specific diseases are well suited to reading and understanding published scientific reports and critiquing their validity.

It is not uncommon to examine how an experiment was performed only to realize that errors were made in the design of the experiment or the interpretation of its results. It takes a group of reviewers with a wide range of expertise to consider the implications of all aspects of the study to recognize the value of the results.

The field of biological effects of electromagnetic energy constitutes a complex combination of scientific disciplines. Many scientific studies in this field do not generate reliable results because they are not based on input from experts in the many fields that affect the interactions between electromagnetic energy and biological organisms. Even well designed scientific studies are subject to misinterpretation when the results are presented to a public that does not understand or appreciate the complex interactions that occur between the physical world and biological organisms and how these affect public health.

Since the 1960s there have been thousands of scientific studies that were intended to discover if electromagnetic energy had an adverse affect on biological tissue. A large number of these studies, designed and performed by biologists, did not accurately expose the subjects to known levels of electromagnetic energy. A field of expertise in RF engineering, called dosimetry, was developed to accurately determine the exact field strengths of both electrical and magnetic fields to

which subjects were exposed. It has been imperative that an expert in electromagnetic dosimetry be involved in study design, though even today this requirement is often ignored. The RF Safety committee contains expertise in dosimetry that often discovers experimental errors in published results due to misstatements of the amount of exposure that subjects experienced.

Epidemiological studies have the potential to recognize disease trends in populations. However, they can also develop misleading results. Epidemiology looks for health trends among people with similar types of exposures as compared to a similar group of people that does not have the same type of exposure. (This type of study has become difficult to perform with cellular telephones because it is hard to find people who do not use them). The great diversity of the population makes it difficult to know that there is not some other exposure that affects the study group. The RF Safety committee contains expertise in epidemiology to make sense of claims based on epidemiological evidence, and the review of the methods and results can reveal a lesser impact of the study than the author or the press had implied.

Some experimental studies correctly demonstrate biological changes due to exposure to electromagnetic fields. A change in a biological tissue that occurs because of the presence of some form of energy may be an interesting finding, but it does not imply that this change will lead to a public health problem. (An obvious example is contraction of the eye pupil in the presence of bright light, a form of electromagnetic energy). The RF Safety Committee contains expertise in Public Health that helps to determine if there may be a correlation between a laboratory finding and any potential concern for the health of people in our society.

The ARRL RF Safety Committee serves as a resource to the ARRL Board of Directors, providing advice that helps them formulate ARRL policy related to RF safety. The RFSC interacts with the ARRL HQ staff to ensure that RF safety is appropriately addressed in ARRL publications and on the ARRL website. The Amateur Radio community corresponds with the RFSC for help with RF safety-related questions and problems. RFSC members monitor and analyze relevant published research. Its members participate in standards coordinating committees and other expert committees related to RF safety. The RFSC is responsible for writing the RF safety text that is included in ARRL publications. The accuracy of RF safety-related issues in articles submitted to QST and QEX are confirmed by committee members. The RFSC also participates in developing the RF safety questions for FCC amateur question pools and works with the FCC in developing its environmental regulations. Radio amateurs with questions related to RF safety can contact the RFSC via its liaison, Ed Hare, W1RFI, w1rfi@arrl.org. The RFSC maintains a webpage at www.arrl.org/arrl-rf-safety-committee.

ing of concerned scientists and medical doctors, who volunteer to serve the radio amateur community to monitor scientific research and to recommend safe practices.

THERMAL EFFECTS OF RF ENERGY

Body tissues that are subjected to *very high* levels of RF energy may suffer serious heat damage. These effects depend on the frequency of the energy, the power density of the RF field that strikes the body and factors such as the polarization of the wave and the grounding of the body.

At frequencies near the body's natural resonances RF energy is absorbed more efficiently. In adults, the primary resonance frequency is usually about 35 MHz if the person is grounded, and about 70 MHz if insulated from the ground. Various body parts are resonant at different frequencies. Body size thus determines the frequency at which most RF energy is absorbed. As the frequency is moved farther from resonance, RF energy absorption becomes less efficient. Specific absorption rate (SAR) is a measure that takes variables such as resonance into account to describe the rate at which RF energy is absorbed in tissue, typically measured in watts per kilogram of tissue (W/kg).

Maximum permissible exposure (MPE) limits define the maximum electric and magnetic field strengths, and the plane-wave equivalent power densities associated with these fields, that a person may be exposed to without harmful effect, and are based on whole-body SAR safety levels. The safe exposure limits vary with frequency as the efficiency of absorption changes. The MPE limits Safety factors are included to insure that the MPE field strength will never result in an unsafe SAR.

Thermal effects of RF energy are usually not a major concern for most radio amateurs because the power levels normally used tend to be low and the intermittent nature of most amateur transmissions decreases total exposure. Amateurs spend more time listening than transmitting and many amateur transmissions such as CW and SSB use low-dutycycle modes. With FM or RTTY, though, the RF is present continuously at its maximum level during each transmission. It is rare for radio amateurs to be subjected to RF fields strong enough to produce thermal effects, unless they are close to an energized antenna or unshielded power amplifier. Specific suggestions for avoiding excessive exposure are offered later in this chapter.

ATHERMAL EFFECTS OF EMF

Biological effects resulting from exposure to power levels of RF energy that do not generate measurable heat are called *athermal* effects. A number of athermal effects of EMF exposure on biological tissue have been seen in the laboratory. However, to date all athermal effects that have been discovered have had the same features: They are transitory, or go away when the EMF exposure is removed, and they have not been associated with any negative health effects.

28.3.2 Researching Biological Effects of EMF Exposure

The statistical basis of scientific research that confuses many non-scientists is the inability of science to state unequivocally that EMF is safe. Effects are studied by scientists using statistical inference where the "null hypothesis" assumes there is no effect and then tries to disprove this assumption by proving an "alternative hypothesis" that there is an effect. The alternative hypothesis can never be entirely disproved because a scientist cannot examine every possible case, so scientists only end up with a probability that the alternative hypothesis is *not* true. Thus, to be entirely truthful, a scientist can never say that something was proven; with respect to low-level EMF exposure, no scientist can guarantee that it is absolutely safe. At best, science can only state that there is a very low probability that it is unsafe. While scientists accept this truism, many members of the general public who are suspicious of EMF and its effects on humans see this as a reason to continue to be afraid.

There are two types of scientific study that are used to learn about the effects of EMF exposure on mammalian biology: laboratory and epidemiological.

LABORATORY STUDY

Scientists conduct laboratory research using animals to learn about biological mechanisms by which EMF may affect mammals. The main advantage of laboratory studies on the biological effects of EMF is that the exposures can be controlled very accurately.

Some major disadvantages of laboratory study also exist. EMF exposure may not affect the species of animals used in the investigations the same way that humans may respond. A common example of this misdirection occurred with eye research. Rabbits had been used for many years to determine that exposure of the eyes to high levels of EMF could cause cataracts. The extrapolation of these results to humans led to the fear that use of radio would harm one's vision. However, the rabbit's eye is on the surface of its skull while the human eye is buried deep within the bony orbit in the skull. Thus, the human eve receives much less exposure from EMF and is less likely to be damaged by the same exposures that had been used in the laboratory experiments on rabbits.

Some biological processes that affect tissue can take many years to occur and laboratory experiments on animals tend to be of shorter duration, in part because the life spans of most animals are much shorter than that of humans. For instance, a typical laboratory rat can be studied at most for two years, during which it progresses from youth to old age with all of the attendant physiological changes that come from normal aging. A disease process that takes multiple exposures over many years to occur is unlikely to be seen in a laboratory study with small animals.

EPIDEMIOLOGICAL RESEARCH

Epidemiologists look at the health patterns of large groups of people using statistical methods. In contrast to laboratory research, epidemiological research has very poor control of its subjects' exposures to EMF but it has the advantages of being able to analyze the effects of a lifetime of exposure and of being able to average out variations among large populations of subjects. By their basic design, epidemiological studies do not demonstrate cause and effect, nor do they postulate mechanisms of disease. Instead, epidemiologists look for associations between an environmental factor and an observed pattern of illness. Apparent associations are often seen in small preliminary studies that later are shown to have been incorrect. At best, such results are used to motivate more detailed epidemiological studies and laboratory studies that narrow down the search for cause-and-effect.

Some preliminary studies have suggested a weak association between exposure to EMF at home or at work and various malignant conditions including leukemia and brain cancer. A larger number of equally well-designed and performed studies, however, have found no association. Risk ratios as high as 2 have been observed in some studies. This means that the number of observed cases of disease in the test group is up to 2 times the "expected" number in the population. Epidemiologists generally regard a risk ratio of 4 or greater to be indicative of a strong association between the cause and effect under study. For example, men who smoke one pack of cigarettes per day increase their risk for lung cancer tenfold compared to nonsmokers and two packs per day increases the risk to more than 25 times the nonsmokers' risk.

Epidemiological research by itself is rarely conclusive, however. Epidemiology only identifies health patterns in groups — it does not ordinarily determine their cause. There are often confounding factors. Most of us are exposed to many different environmental hazards that may affect our health in various ways. Moreover, not all studies of persons likely to be exposed to high levels of EMF have yielded the same results (see sidebar on preliminary epidemiological studies).

Preliminary Epidemiology

Just about every week you can pick up the newspaper and see a screaming banner headline such as: "Scientists Discover Link Between Radio Waves and Disease." So why are you still operating your ham radio? You've experienced the inconsistency in epidemiological study of diseases. This is something that every radio amateur should understand in order to know how to interpret the real meaning of the science behind the headlines and to help assuage the fears that these stories elicit in others.

Just knowing that someone who uses a radio gets a disease, such as cancer, doesn't tell us anything about the cause-and-effect of that disease. People came down with cancer, and most other diseases, long before radio existed. What epidemiologists try to identify is a group of people who all have a common exposure to something and all suffer from a particular disease in higher proportion than would be expected if they were not exposed. This technique has been highly effective in helping health officials notice excesses of disease due to things such as poisoning of water supplies by local industry and even massive exposures such as smoking. However, epidemiology rarely proves that an exposure causes a disease; rather it provides the evidence that leads to further study.

While the strength of epidemiology is that it helps scientists notice anomalies in entire populations, its weakness is that it is non-specific. An initial epidemiological study examines only two things: suspected exposures and rates of diseases. These studies are relatively simple and inexpensive to perform and may point to an apparent association that then bears further study. For instance, in one study of the causes of death of a selection of Amateur Radio operators, an excess of leukemia was suggested. The percentage of ham radio operators who died of leukemia in that study was higher than expected based on the percentage of the rest of the population that died of leukemia. By itself, this has little meaning and should not be a cause for concern, since the study did not consider anything else about the sample population except that they had ham licenses. Many other questions arise: Were the study subjects exposed to any unusual chemicals? Did any of the study subjects have a family history of leukemia? Did the licensed amateurs even operate radios, what kind and how often? To an epidemiologist, this result might provide enough impetus to raise the funds to gather more specific information about each subject and perform a more complete study that strengthens the apparent associations. However, a slight excess of disease in a preliminary study rarely leads to further study. Commonly, an epidemiologist does not consider a preliminary study to be worth pursuing unless the ratio of excess disease, also called the risk ratio, is 4:1 or greater. Unfortunately, most news reporters are not epidemiologists and do not understand this distinction. Rather, a slight excess of disease in a preliminary study can lead to banner headlines that raise fear in the society, causing unreasonable resistance to things like cell phones and ham radios.

Headlines that blow the results of preliminary epidemiological studies out of proportion are rarely followed by retractions that are as visible if the study is followed up by one that is more complete and shows no association with disease. In the case of the aforementioned epidemiological study of hams' licensing and death records, overblown publicity about the results has led to the urban legend that ham radio operators are likely to come down with leukemia. Not only is this an unfounded conclusion due to the preliminary nature of the original study, but a similar study was recently performed by the National Cancer Institute using a far larger number of subjects and no significant excess of any disease was found. Hams should be able to recognize when sensationalistic headlines are based on inconclusive science and should be prepared to explain to their families, friends and neighbors just how inconclusive such results are.

28.3.3 Safe Exposure Levels

How much EMF energy is safe? Scientists and regulators have devoted a great deal of effort to deciding upon safe RF-exposure limits. This is a very complex problem, involving difficult public health and economic considerations. The recommended safe levels have been revised downward several times over the years — and not all scientific bodies agree on this question even today. The latest Institute of Electrical and Electronics Engineers (IEEE) C95.1 standard for recommended radio frequency exposure limits was published in

2006, updating one that had previously been published in 1991 and adopted by the American National Standards Institute (ANSI) in 1992. In the new standard changes were made to better reflect the current research, especially related to the safety of cellular telephones. At some frequencies the new standard determined that higher levels of exposure than previously thought are safe (see sidebar, "Where Do RF Safety Standards Come From?").

The IEEE C95.1 standard recommends frequency-dependent and time-dependent maximum permissible exposure levels. Unlike earlier versions of the standard, the 1991

and 2006 standards set different RF exposure limits in *controlled environments* (where energy levels can be accurately determined and everyone on the premises is aware of the presence of EM fields) and in *uncontrolled environments* (where energy levels are not known or where people may not be aware of the presence of EM fields). FCC regulations adopted these concepts to include controlled/occupational and uncontrolled/general population exposure limits.

The graph in Figure 28.22 depicts the 1991 IEEE standard (which is still used as the basis of FCC regulation). It is necessarily a complex graph, because the standards differ not only for controlled and uncontrolled environments but also for electric (E) fields and magnetic (H) fields. Basically, the lowest E-field exposure limits occur at frequencies between 30 and 300 MHz. The lowest H-field exposure levels occur at 100-300 MHz. The ANSI standard sets the maximum E-field limits between 30 and 300 MHz at a power density of 1 mW/cm² (61.4 V/m) in controlled environments — but at one-fifth that level (0.2 mW/cm² or 27.5 V/m) in uncontrolled environments. The H-field limit drops to 1 mW/cm² (0.163 A/m) at 100-300 MHz in controlled environments and 0.2 mW/cm² (0.0728 A/m) in uncontrolled environments. Higher power densities are permitted at frequencies below 30 MHz (below 100 MHz for H fields) and above 300 MHz, based on the concept that the body will not be resonant at those frequencies and will therefore absorb less energy.

In general, the ANSI/IEEE standard requires averaging the power level over time periods ranging from 6 to 30 minutes for power-density calculations, depending on the frequency and other variables. The ANSI/ IEEE exposure limits for uncontrolled environments are lower than those for controlled environments, but to compensate for that the standard allows exposure levels in those environments to be averaged over much longer time periods (generally 30 minutes). This long averaging time means that an intermittent RF source (such as an Amateur Radio transmitter) will result in a much lower exposure than a continuous-duty station, with all other parameter being equal. Time averaging is based on the concept that the human body can withstand a greater rate of body heating (and thus, a higher level of RF energy) for a short time.

Another national body in the United States, the National Council for Radiation Protection and Measurement (NCRP), also has adopted recommended exposure guidelines. NCRP urges a limit of 0.2 mW/cm² for nonoccupational exposure in the 30- 300 MHz range. The NCRP guideline differs from IEEE in that it takes into account the effects of modu-

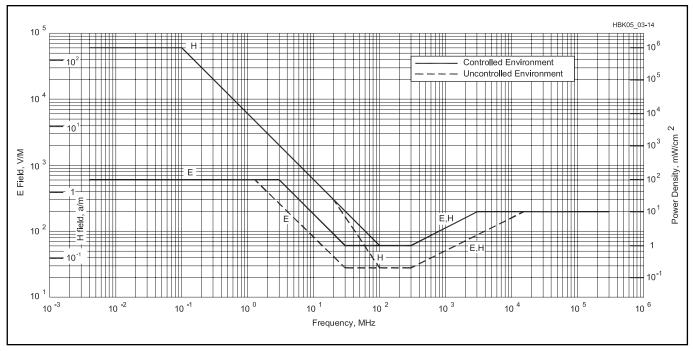

Figure 28.22 — 1991 RF protection guidelines for body exposure of humans. It is known officially as the "IEEE Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz."

Where Do RF Safety Standards Come From?

So much of the way we deal with RF Safety is based on "Safety Standards." The FCC environmental exposure regulations that every ham must follow are largely restatements of the conclusions reached by some of the major safety standards. How are these standards developed and why should we trust them?

The preeminent RF safety standard in the world was developed by the Institute of Electrical and Electronics Engineers (IEEE). The most recent edition is entitled C95.1 -2005: IEEE Standard for Safety Levels with Respect to Human Exposure to Radio Frequency Electromagnetic Fields, 3 kHz to 300 GHz. The IEEE C95.1 Standard has a long history. The first C95.1 RF safety standard was released in 1966, was less than 2 pages long and listed no references. It essentially said that for frequencies between 10 MHz and 100 GHz people should not be exposed to a power density greater than 10 mW/cm². The C95.1 standard was revised in 1974, 1982, 1991 and 2005. The latest (2005) edition of the standard was published in 2006, is 250 pages long and has 1143 references to the scientific literature. Most of the editions of the IEEE C95.1

standard were adopted by the American National Standards Institute (ANSI) a year or two after they were published by IEEE. The 2005 edition was adopted by ANSI in 2006.

The committee at IEEE that developed the latest revision to C95.1 is called International Committee on Electromagnetic Safety Technical Committee 95 Subcommittee 4 and had a large base of participants. The subcommittee was co-chaired by C-K Chou, Ph.D., of Motorola Laboratories, and John D'Andrea, PhD, of the U.S. Naval Health Research Center. The committee had 132 members, 42% of whom were from 23 countries outside the United States. The members of the committee represented academia (27%), government (34%), industry (17%), consultants (20%) and the general public (2%).

Early editions of C95.1 were based on the concept that heat generated in the body should be limited to prevent damage to tissue. Over time the standard evolved to protect against all known adverse biological effects regardless of the amount of heat generated. The 2005 revision was based on

the principles that the standard should protect human health yet still be practical to implement, its conclusions should be based solely on scientific evidence and wherever scientifically defensible it should be harmonized with other international RF safety standards. It based its conclusions on 50 years of scientific study. From over 2500 studies on EMF performed during that time, 1300 were selected for their relevance to the health effects of RF exposure. The science in these studies was evaluated for its quality and methodology and 1143 studies were referenced in producing the latest standard.

Other major standards bodies have published similar standards. The National Council for Radiation Protection and Measurement (NCRP) published its safety standard entitled, Report No. 86: Biological Effects and Exposure Criteria for Radiofrequency Electromagnetic Fields in 1986. The International Commission on Non-Ionizing Radiation Protection (ICNIRP) published its safety standard entitled Guidelines for Limiting Exposure to Time-Varying Electric, Magnetic, and Electromagnetic Fields (Up to 300 GHz) in 1998.

FCC RF Exposure Regulations

FCC regulations control the amount of RF exposure that can result from your station's operation (§§97.13, 97.503, 1.1307 (b)(c)(d), 1.1310, 2.1091 and 2.1093). The regulations set limits on the maximum permissible exposure (MPE) allowed from operation of transmitters in all radio services. They also require that certain types of stations be evaluated to determine if they are in compliance with the MPEs specified in the rules. The FCC has also required that questions on RF environmental safety practices be added to Technician and General license examinations.

THE RULES

Maximum Permissible Exposure (MPE)

All radio stations regulated by the FCC must comply with the requirements for MPEs, even QRP stations running only a few watts or less. The MPEs vary with frequency, as shown in **Table A**. MPE limits are specified in maximum electric and magnetic fields for frequencies below 30 MHz, in power density for frequencies above 300 MHz and all three ways for frequencies from 30 to 300 MHz. For compliance purposes, all of these limits must be considered separately. If any one is exceeded, the station is not in compliance. In effect, this means that both electric and magnetic field must be determined below 300 MHz but at higher frequencies determining either the electric or magnetic field is normally sufficient.

The regulations control human exposure to RF fields, not the strength of RF fields in any space. There is no limit to how strong a field can be as long as no one is being exposed to it, although FCC regulations require that amateurs use the minimum necessary power at all times (§97.311 [a]).

Table A (From §1.1310) Limits for Maximum Permissible Exposure (MPE)

(A) Limits for Occupational/Controlled Exposure

Frequency Range	Electric Field	Magnetic Field	Power Density	Averaging Time
(MHz)	Strength (V/m)	Strength (A/m)	(mW/cm²)	(minutes)
0.3-3.0	614	1.63	(100)*	6
3.0-30	1842/f	4.89/f	(900/f ²)*	6
30-300	61.4	0.163	1.0	6
300-1500	_	_	f/300	6
1500-100,000	_	_	5	6

f = frequency in MHz

(B) Limits for General Population/Uncontrolled Exposure

Frequency Range (MHz)	Electric Field Strength (V/m)	Magnetic Field Strength (A/m)	Power Density (mW/cm²)	Averaging Time (minutes)
'	Oli Crigili (V/III)	Olicingui (Aviii)	'	(minutes)
0.3-1.34	614	1.63	(100)*	30
1.34-30	824/f	2.19/f	(180/f ²)*	30
30-300	27.5	0.073	0.2	30
300-1500	_	_	f/1500	30
1500-100,000	_	_	1.0	30

f = frequency in MHz

Note 1: This means the equivalent far-field strength that would have the E or H-field component calculated or measured. It does not apply well in the near field of an antenna. The equivalent far-field power density can be found in the near or far field regions from the relationships: $P_d = |E_{total}|^2 / 3770 \text{ mW/cm}^2$ or from $P_d = |H_{total}|^2 \times 37.7 \text{ mW/cm}^2$.

Note 2:
$$|E_{total}|^2 = |E_x|^2 + |E_y|^2 + |E_z|^2$$
, and $|H_{total}|^2 = |H_x|^2 + |H_y|^2 + |H_z|^2$

Environments

The FCC has defined two tiers of exposure limits — occupational/controlled limits and general population/uncontrolled limits. Occupational/controlled limits apply when people are exposed as a condition of their employment and when they are aware of that exposure and can take steps to minimize it, if appropriate. General population/uncontrolled limits apply to exposure of the general public or people who are not normally aware of the exposure or can-

not exercise control over it. The limits for general population/uncontrolled exposure are more stringent than the limits for occupational/controlled exposure. Specific definitions of the exposure categories can be found in Section 1.1310 of the FCC rules.

Although occupational/controlled limits are usually applicable in a workplace environment, the FCC has determined that they generally apply to amateur operators and members of their immediate households. In most cases, occupational/

lation on an RF carrier.

The FCC MPE regulations are based on a combination of the 1992 ANSI/IEEE standard and 1986 NCRP recommendations. The MPE limits under the regulations are slightly different than the ANSI/IEEE limits and do not reflect all the assumptions and exclusions of the ANSI/IEEE standard.

28.3.4 Cardiac Pacemakers and RF Safety

It is a widely held belief that cardiac pacemakers may be adversely affected in their function by exposure to electromagnetic fields. Amateurs with pacemakers may ask whether their operating might endanger themselves or visitors to their shacks who have a pacemaker. Because of this, and similar concerns regarding other sources of EM fields, pacemaker manufacturers apply design methods that for the most part shield the pacemaker circuitry from even relatively high EM field strengths.

It is recommended that any amateur who has a pacemaker, or is being considered for one, discuss this matter with his or her physician. The physician will probably put the amateur into contact with the technical representative of the pacemaker manufacturer. These representatives are generally excellent resources, and may have data from laboratory or "in the field" studies with specific model pacemakers.

One study examined the function of a mod-

ern (dual chamber) pacemaker in and around an Amateur Radio station. The pacemaker generator has circuits that receive and process electrical signals produced by the heart, and also generate electrical signals that stimulate (pace) the heart. In one series of experiments, the pacemaker was connected to a heart simulator. The system was placed on top of the cabinet of a 1-kW HF linear amplifier during SSB and CW operation. In another test, the system was placed in close proximity to several 1 to 5-W 2-meter hand-held transceivers. The test pacemaker was connected to the heart simulator in a third test, and then placed on the ground 9 meters below and 5 meters in front of a three-element Yagi HF antenna. No interference with pacemaker function was

^{* =} Plane-wave equivalent power density (see Notes 1 and 2).

^{* =} Plane-wave equivalent power density (see Notes 1 and 2).

controlled limits can be applied to your home and property to which you can control physical access. The general population/uncontrolled limits are intended for areas that are accessible by the general public, such as your neighbors' properties.

The MPE levels are based on average exposure. An averaging time of 6 minutes is used for occupational/controlled exposure; an averaging period of 30 minutes is used for general population/uncontrolled exposure.

Station Evaluations

The FCC requires that certain amateur stations be evaluated for compliance with the MPEs. Although an amateur can have someone else do the evaluation, it is not difficult for hams to evaluate their own stations. The ARRL book RF Exposure and You contains extensive information about the regulations and a large chapter of tables that show compliance distances for specific antennas and power levels. Generally, hams will use these tables to evaluate their stations. Some of these tables have been included in the FCC's information — OET Bulletin 65 and its Supplement B (available for downloading at the FCC's RF Safety website). If hams choose, however, they can do more extensive calculations, use a computer to model their antenna and exposure, or make actual measurements.

Categorical Exemptions

Some types of amateur stations do not need to be evaluated, but these stations must still comply with the MPE limits. The station licensee remains responsible for ensuring that the station meets these requirements.

The FCC has exempted these stations from the evaluation requirement because their output power, operating

mode and frequency are such that they are presumed to be in compliance with the rules.

Stations using power equal to or less than the levels in **Table B** do not have to be evaluated on a routine basis. For the 100-W HF ham station, for example, an evaluation would be required only on 12 and 10 meters.

Hand-held radios and vehicle-mounted mobile radios that operate using a pushto-talk (PTT) button are also categorically exempt from performing the routine evaluation.

Repeater stations that use less than 500 W ERP or those with antennas not mounted on buildings; if the antenna is at least 10 meters off the ground, also do not need to be evaluated.

Correcting Problems

Most hams are already in compliance with the MPE requirements. Some amateurs, especially those using indoor antennas or high-power, high-duty-cycle modes such as a RTTY bulletin station and specialized stations for moon bounce operations and the like may need to make adjustments to their station or operation to be in compliance.

The FCC permits amateurs considerable flexibility in complying with these regulations. As an example, hams can adjust their operating frequency, mode or power to comply with the MPE limits. They can also adjust their operating habits or control the direction their antenna is pointing.

More Information

This discussion offers only an overview of this topic; additional information can be found in *RF Exposure and You* and on the ARRL website at **www.arrl.org/rf-exposure**. The ARRL website has links to the FCC website, with OET Bulletin 65 and Supplement B and links to software that hams can use to evaluate their stations.

Table B Power Thresholds for Routine Evaluation of Amateur Radio Stations

Evaluation Required if

Wavelength

Band	Power* (watts) Exceeds:
MF	
160 m	500
HF	
80 m	500
75 m	500
40 m	500
30 m	425
20 m	225
17 m	125
15 m	100
12 m	75
10 m	50
VHF (all bands)	50
UHF	
70 cm	70
33 cm	150
23 cm	200
13 cm	250
SHF (all bands)	250
EHF (all bands)	250

Repeater stations Non-building-mounted (all bands) antennas:

height above ground level to lowest point of antenna < 10 m and power > 500 W ERP Building-mounted antennas: power > 500 W ERP

*Transmitter power = Peak-envelope power input to antenna. For repeater stations only, power exclusion based on ERP (effective radiated power).

observed in these experiments.

Although the possibility of interference cannot be entirely ruled out by these few observations, these tests represent more severe exposure to EM fields than would ordinarily be encountered by an amateur — with an average amount of common sense. Of course prudence dictates that amateurs with pacemakers, who use handheld VHF transceivers, keep the antenna as far as possible from the site of the implanted pacemaker generator. They also should use the lowest transmitter output required for adequate communication. For high power HF transmission, the antenna should be as far as possible from the operating position, and all equipment should be properly grounded.

28.3.5 Low-Frequency Fields

There has been considerable laboratory research about the biological effects of power line EMF. For example, some separate studies have indicated that even fairly low levels of EMF exposure might alter the human body's circadian rhythms, affect the manner in which T lymphocytes function in the immune system and alter the nature of the electrical and chemical signals communicated through the cell membrane and between cells, among other things. Although these studies are intriguing, they do not demonstrate any effect of these low-level fields on the overall organism.

Much of this research has focused on lowfrequency magnetic fields, or on RF fields that are keyed, pulsed or modulated at a low audio frequency (often below 100 Hz). Several studies suggested that humans and animals could adapt to the presence of a steady RF carrier more readily than to an intermittent, keyed or modulated energy source.

The results of studies in this area, plus speculations concerning the effect of various types of modulation, were and have remained somewhat controversial. None of the research to date has demonstrated that low-level EMF causes adverse health effects.

Given the fact that there is a great deal of ongoing research to examine the health consequences of exposure to EMF, the American Physical Society (a national group of highly respected scientists) issued a statement in May 1995 based on its review of available

data pertaining to the possible connections of cancer to 60-Hz EMF exposure. Their report is exhaustive and should be reviewed by anyone with a serious interest in the field. Among its general conclusions are the following:

- 1. The scientific literature and the reports of reviews by other panels show no consistent, significant link between cancer and power line fields.
- 2. No plausible biophysical mechanisms for the systematic initiation or promotion of cancer by these extremely weak 60-Hz fields have been identified.
- 3. While it is impossible to prove that no deleterious health effects occur from exposure to any environmental factor, it is necessary to demonstrate a consistent, significant, and causal relationship before one can conclude that such effects do occur.

In a report dated October 31, 1996, a committee of the National Research Council of the National Academy of Sciences has concluded that no clear, convincing evidence exists to show that residential exposures to electric and magnetic fields (EMF) are a threat to human health.

A National Cancer Institute epidemiological study of residential exposure to magnetic fields and acute lymphoblastic leukemia in children was published in the *New England Journal of Medicine* in July 1997. The exhaustive, seven-year study concludes that if there is any link at all, it is far too weak to be of concern.

In 1998, the US National Institute on Environmental Health Sciences organized a working group of experts to summarize the research on power-line EMF. The committee used the classification rules of the International Agency for Research on Cancer (IARC) and performed a meta-analysis to combine all past results as if they had been performed in a single study. The NIEHS working group concluded that the research did not show this type of exposure to be a carcinogen but could not rule out the possibility either. Therefore, they defined power-line EMF to be a Class 2b carcinogen under the IARC classification. The definition, as stated by the IARC is: "Group 2B: The agent is possibly carcinogenic to humans. There is limited pidemiological evidence plus limited or inadequate animal evidence." Other IARC Class 2b carcinogens include automobile exhaust, chloroform, coffee, ceramic and glass fibers, gasoline and pickled vegetables.

Readers may want to follow this topic as further studies are reported. Amateurs should be aware that exposure to RF and ELF (60 Hz) electromagnetic fields at all power levels and frequencies has not been fully studied under all circumstances. "Prudent avoidance" of any avoidable EMF is always a good idea. Prudent avoidance doesn't mean that amateurs should

Table 28.4

Typical 60-Hz Magnetic Fields Near Amateur Radio Equipment and ACPowered Household Appliances

Values are in milligauss.

Item	Field	Distance
Electric blanket	30-90	Surface
Microwave oven	10-100	Surface
	1-10	12 in.
IBM personal computer	5-10	Atop monitor
	0-1	15 in. from screen
Electric drill	500-2000	At handle
Hair dryer	200-2000	At handle
HF transceiver	10-100	Atop cabinet
	1-5	15 in. from front
1-kW RF amplifier	80-1000	Atop cabinet
	1-25	15 in. from front

Table 28.5
Typical RF Field Strengths Near Amateur Radio Antennas

A sampling of values as measured by the Federal Communications Commission and Environmental Protection Agency, 1990

Antenna Type	Freq (MHz)	Power (W)	E Field (V/m)	Location
Dipole in attic	14.15	100	7-100	In home
Discone in attic	146.5	250	10-27	In home
Half sloper	21.5	1000	50	1 m from base
Dipole at 7-13 ft	7.14	120	8-150	1-2 m from earth
Vertical	3.8	800	180	0.5 m from base
5-element Yagi at 60 ft	21.2	1000	10-20	In shack
			14	12 m from base
3-element Yagi at 25 ft	28.5	425	8-12	12 m from base
Inverted V at 22-46 ft	7.23	1400	5-27	Below antenna
Vertical on roof	14.11	140	6-9	In house
			35-100	At antenna tuner
Whip on auto roof	146.5	100	22-75	2 m antenna
			15-30	In vehicle
			90	Rear seat
5-element Yagi at 20 ft	50.1	500	37-50	10 m antenna

be fearful of using their equipment. Most amateur operations are well within the MPE limits. If any risk does exist, it will almost surely fall well down on the list of causes that may be harmful to your health (on the other end of the list from your automobile). It does mean, however, that hams should be aware of the potential for exposure from their stations, and take whatever reasonable steps they can take to minimize their own exposure and the exposure of those around them.

Although the FCC doesn't regulate 60-Hz fields, some recent concern about EMF has focused on 60 Hz. Amateur Radio equipment can be a significant source of 60 Hz fields, although there are many other sources of this kind of energy in the typical home. Magnetic fields can be measured relatively accurately with inexpensive 60-Hz meters that are made by several manufacturers.

Table 28.4 shows typical magnetic field intensities of Amateur Radio equipment and various household items.

28.3.6 Determining RF Power Density

Unfortunately, determining the power density of the RF fields generated by an amateur station is not as simple as measuring low-frequency magnetic fields. Although sophisticated instruments can be used to measure RF power densities quite accurately, they are costly and require frequent recalibration. Most amateurs don't have access to such equipment, and the inexpensive field-strength meters that we do have are not suitable for measuring RF power density.

Table 28.5 shows a sampling of measurements made at Amateur Radio stations by the Federal Communications Commission and the Environmental Protection Agency in 1990. As this table indicates, a good antenna well removed from inhabited areas poses no hazard under any of the ANSI/IEEE guidelines. However, the FCC/EPA survey also indicates that amateurs must be careful about using indoor

or attic-mounted antennas, mobile antennas, low directional arrays or any other antenna that is close to inhabited areas, especially when moderate to high power is used.

Ideally, before using any antenna that is in close proximity to an inhabited area, you should measure the RF power density. If that is not feasible, the next best option is make the installation as safe as possible by observing the safety suggestions listed in **Table 28.6**.

It also is possible, of course, to calculate the probable power density near an antenna using simple equations. Such calculations have many pitfalls. For one, most of the situations where the power density would be high enough to be of concern are in the near field. In the near field, ground interactions and other variables produce power densities that cannot be determined by simple arithmetic. In the far field, conditions become easier to predict with simple calculations. (See the February 2013 QST article "Q and the Energy Stored Around Antennas" by Kai Siwiak, KE4PT and the Antennas chapter of this book for more information about stored energy density near antennas.)

The boundary between the near field and the far field depends on the wavelength of the transmitted signal and the physical size and configuration of the antenna. The boundary between the near field and the far field of an antenna can be as much as several wavelengths from the antenna.

Computer antenna-modeling programs are another approach you can use. *MININEC* or other codes derived from *NEC* (Numerical Electromagnetics Code) are suitable for estimating RF magnetic and electric fields around amateur antenna systems.

These models have limitations. Ground interactions must be considered in estimating near-field power densities, and the "correct ground" must be modeled. Computer modeling is generally not sophisticated enough to predict "hot spots" in the near field — places where the field intensity may be far higher than would be expected, due to reflections from nearby objects. In addition, "nearby objects" often change or vary with weather or the season, therefore the model so laboriously crafted may not be representative of the actual situation, by the time it is running on the computer.

Intensely elevated but localized fields often can be detected by professional measuring instruments. These "hot spots" are often found near wiring in the shack, and metal objects such as antenna masts or equipment cabinets. But even with the best instrumentation, these measurements also may be misleading

in the near field. One need not make precise measurements or model the exact antenna system, however, to develop some idea of the relative fields around an antenna. Computer modeling using close approximations of the geometry and power input of the antenna will generally suffice. Those who are familiar with MININEC can estimate their power densities by computer modeling, and those who have access to professional power-density meters can make useful measurements.

While our primary concern is ordinarily the intensity of the signal radiated by an antenna, we also should remember that there are other potential energy sources to be considered. You also can be exposed to excessive RF fields directly from a power amplifier if it is operated without proper shielding. Transmission lines also may radiate a significant amount of energy under some conditions. Poor microwave waveguide joints or improperly assembled connectors are another source of incidental exposure.

28.3.7 Further RF Exposure Suggestions

Potential exposure situations should be taken seriously. Based on the FCC/EPA measurements and other data, the "RF awareness" guidelines of Table 28.6 were developed by the ARRL RF Safety Committee. A longer version of these guidelines, along with a complete list of references, appeared in a *QST* article by Ivan Shulman, MD, WC2S ("Is Amateur Radio Hazardous to Our Health?" *QST*, Oct 1989, pp 31-34).

In addition, the ARRL has published a book, *RF Exposure and You* that helps hams comply with the FCC's RF-exposure regulations. The ARRL also maintains an RF-exposure news page on its website. See **www.arrl.org/rf-exposure**. This site contains reprints of selected *QST* articles on RF exposure and links to the FCC and other useful sites.

SUMMARY

The ideas presented in this chapter are intended to reinforce the concept that ham radio, like many other activities in modern life, does have certain risks. But by understanding the hazards and how to deal effectively with them, the risk can be minimized. Common-sense measures can go a long way to help us prevent accidents. Traditionally, amateurs are inventors, and experimenting is a major part of our nature. But reckless chance-taking is never wise, especially when our health and well-being is involved. A healthy attitude toward doing things the right way will help us meet our goals and expectations.

Table 28.6 RF Awareness Guidelines

These guidelines were developed by the ARRL RF Safety Committee, based on the FCC/EPA measurements of Table 28.4 and other data.

- Although antennas on towers (well away from people) pose no exposure problem, make
 certain that the RF radiation is confined to the antennas' radiating elements themselves.
 Provide a single, good station ground (earth), and eliminate radiation from transmission lines.
 Use good coaxial cable or other feed line properly. Avoid serious imbalance in your antenna
 system and feed line. For high-powered installations, avoid end-fed antennas that come directly
 into the transmitter area near the operator.
- No person should ever be near any transmitting antenna while it is in use. This is especially true for mobile or ground-mounted vertical antennas. Avoid transmitting with more than 25 W in a VHF mobile installation unless it is possible to first measure the RF fields inside the vehicle. At the 1-kW level, both HF and VHF directional antennas should be at least 35 ft above inhabited areas. Avoid using indoor and attic-mounted antennas if at all possible. If open-wire feeders are used, ensure that it is not possible for people (or animals) to come into accidental contact with the feed line.
- Don't operate high-power amplifiers with the covers removed, especially at VHF/UHF.
- In the UHF/SHF region, never look into the open end of an activated length of waveguide or microwave feed-horn antenna or point it toward anyone. (If you do, you may be exposing your eyes to more than the maximum permissible exposure level of RF radiation.) Never point a high-gain, narrow-bandwidth antenna (a paraboloid, for instance) toward people. Use caution in aiming an EME (moonbounce) array toward the horizon; EME arrays may deliver an effective radiated power of 250,000 W or more.
- With hand-held transceivers, keep the antenna away from your head and use the lowest power possible to maintain communications. Use a separate microphone and hold the rig as far away from you as possible. This will reduce your exposure to the RF energy.
- Don't work on antennas that have RF power applied.
- Don't stand or sit close to a power supply or linear amplifier when the ac power is turned on. Stay at least 24 inches away from power transformers, electrical fans and other sources of high-level 60-Hz magnetic fields.

Space Communications

Radio amateurs point their antennas skyward to talk via communications satellites built by groups of interested and talented hams. In the first part of this 2018 supplement, Patrick Stoddard, WD9EWK, updates material previously contributed by Steve Ford, WB8IMY, providing background and showing what you need to start using the amateur satellites.

The EME section, updated for the 2018 edition by Joe Taylor, K1JT, discusses the requirements for successful contacts via the EME path. K1JT gratefully acknowledges input and advice for the EME section from Allen Katz, K2UYH, Marc Franco, N2UO, Peter Blair, G3LTF, Graham Daubney, F5VHX, Lionel Edwards, VE7BQH, Ian White, GM3SEK, Leif Asbrink, SM5BSZ and Rex Moncur, VK7MO.

A glossary of space communications terms may be found at the end of this chapter. Unless otherwise noted, references to other chapters are to chapters in the print version of the ARRL Handbook.

1 Amateur Satellite History

Many people are astonished to discover that Amateur Radio satellites are not new. In fact, the story of Amateur Radio satellites is as old as the Space Age itself.

The Space Age is said to have begun on October 4, 1957. That was the day when the Soviet Union shocked the world by launching Sputnik 1, the first artificial satellite. Hams throughout the world monitored Sputnik's telemetry beacons at 20.005 and 40.002 MHz as it orbited the Earth. During Sputnik's 22-day voyage, Amateur Radio was in the media spotlight since hams were among the few civilian sources of news about the revolutionary spacecraft.

Almost four months later, the United States responded with the launch of the Explorer 1 satellite on January 31, 1958. At about that same time, a group of Amateur Radio operators on the West Coast began considering the possibility of a ham satellite. This group later organized itself as Project OSCAR (OSCAR is an acronym meaning Orbiting Satellite Carrying Amateur Radio) with the expressed aim of building and launching amateur satellites.

After a series of high-level exchanges with the American Radio Relay League and the United States Air Force, Project OSCAR secured a launch opportunity. The first Amateur Radio satellite, known as OSCAR 1, would "piggyback" with the Discoverer 36 spacecraft being launched from Vandenberg Air Force Base in California. Both "birds" (as satellites are called among their builders and users) successfully reached low Earth orbit on the morning of December 12, 1961.

OSCAR 1 weighed only 10 pounds. It was built, quite literally, in the basements and garages of the Project OSCAR team. It carried a small beacon transmitter that allowed ground stations to measure radio propagation through the ionosphere. The beacon also transmitted telemetry indicating the internal temperature of the satellite.

OSCAR 1 was an overwhelming success. More than 570 amateurs in 28 countries forwarded observations to the Project OSCAR data collection center. OSCAR 1 lasted only 22 days in orbit before burning up as it reentered the atmosphere, but Amateur Radio's "low tech" entry into the high tech world of space travel had been firmly secured. When scientific groups asked the Air Force for advice on secondary payloads, the Air Force suggested they study the OSCAR design. What's more, OSCAR 1's bargain-basement procurement approach and management philosophy would become the hallmark of all the OSCAR satellite projects that followed, even to this day.

Since then, amateurs have successfully built and launched dozens of satellites, each one progressively more sophisticated than the last.

1.1 AMSAT

Much of the amateur satellite progress has been spearheaded by the Radio Amateur Satellite Corporation, better known as *AMSAT*. The original AMSAT was formed in Washington, DC in 1969 as an organization dedicated to fostering an Amateur Radio presence in space. The AMSAT model quickly became international with many countries creating their own AMSAT organizations, such as AMSAT-UK in England, AMSAT-DL in Germany, BRAMSAT in Brazil and AMSAT-LU in Argentina. All of these organizations operate independently but may cooperate on large satellite projects and other items of interest to the worldwide Amateur Radio satellite community. Because of the many AMSAT organizations now in existence, the US AMSAT organization is frequently designated AMSAT-NA.

Since the very first OSCAR satellites were launched in the early 1960s, AMSAT's inter-

Table 1					
Currently	Active	Amateur	Radio	Satellites	

Currently Active Amateur	Radio Satellites		
Satellite	Uplink (MHz)	Downlink (MHz)	Mode
AMSAT-OSCAR 7	145.850-145.950	29.400-29.500	SSB/CW, non-inverting transponder
	432.175-432.125	145.925-145.975	SSB/CW, inverting transponder
		29.502	CW beacon
		145.975	CW beacon
		435.100	RTTY beacon (occasionally heard)
AMSAT-OSCAR 73	435.150-435.130	145.950-145.970	SSB/CW, inverting transponder
AMSAI-OSCAIT 75	400.100-400.100	145.935	BPSK telemetry
AMSAT-OSCAR 85	40F 170		FM repeater with telemetry
	435.170	145.980	FM, crew contacts (ITU Region 1 only)
ARISS (ISS)	145.200	145.800	
	144.490	145.800	FM, crew contacts
		4.45.000	(ITU Regions 2 & 3)
		145.800	SSTV transmissions
	145.825	145.825	1200bps APRS digipeater
	437.550	437.550	1200bps APRS digipeater
			(alternate frequency)
	437.800	145.800	FM repeater (rarely used)
EO-79 (QB50p1/FUNcube-2)	435.077-435.047	145.935-145.965	SSB/CW, inverting transponder
		145.815	CW beacon or BPSK telemetry
EO-88 (Nayif-1/FUNcube-3)	435.045-435.015	145.960-145.990	SSB/CW, inverting transponder
,		145.940	BPSK telemetry
Fuji-OSCAR 29 (FO-29)	146.000-145.900	435.800-435.900	SSB/CW, inverting transponder
, , ,		435.795	CW beacon
LilacSat-2 (CAS-3H)	144.350	437.200	FM repeater (occasionally activated)
LU-87 (LUSEX/NuSat-1)	435.965-435.935	145.935-145.965	SSB/CW, inverting transponder
,		145.900	CW beacon
Navy-OSCAR 44	145.825	145.825	1200/9600 bps APRS digipeater
New-OSCAR 84 (PSAT)	145.825	145.825	1200bps APRS digipeater
	28.120	435.350	PSK31 transponder (FM downlink)
Saudi-OSCAR 50	145.850	436.795	FM repeater (67 Hz CTCSS required)
Ukube-1 (FUNcube-2)	435.080-435.060	145.930-145.950	SSB/CW, inverting transponder
Chabe I (I Civoabe 2)	400.000 400.000	145.840	CW beacon or digital telemetry
		145.915	BPSK telemetry
XW-2A (CAS-3A)	435.050-435.030	145.665-145.685	SSB/CW, inverting transponder
AW-2A (OAO-0A)	455.050-455.050	145.640	Digital telemetry
		145.660	CW beacon
VIM OR (CAC OR)	435.110-435.090	145.730-145.750	SSB/CW, inverting transponder
XW-2B (CAS-3B)	435.110-435.090		
		145.705	Digital telemetry

		145.770	Digital telemetry
		145.790	CW beacon
XW-2D (CAS-3D)	435.230-435.210	145.860-145.880	SSB/CW, inverting transponder
		145.835	Digital telemetry
		145.855	CW beacon
XW-2F (CAS-3F)	435.350-435.330	145.980-146.000	SSB/CW, inverting transponder
		145.955	Digital telemetry
		145.975	CW beacon
Information from AMSAT as of N	March 2017		

Information from AMSAT, as of March 2017.

For information on current satellite status and development programs, along with other amateur satellites which only transmit telemetry, please see **www.amsat.org**.

national volunteers have pioneered a wide variety of new communications technologies. These breakthroughs have included some of the very first satellite voice transponders as well as highly advanced digital "store-and-forward" messaging transponder techniques. All of these accomplishments have been achieved through close cooperation with international space agencies that often have provided launch opportunities at significantly reduced costs in return for AMSAT's technical assistance in developing new ways to launch paying customers.

AMSAT's major source of operating rev-

enue is obtained by offering memberships in the various international AMSAT organizations. Membership is open to radio amateurs and to others interested in the amateur exploration of space. Modest donations are also sought for tracking software and other satellite related publications. In addition, specific spacecraft development funds are established from time to time to help fund major AMSAT spacecraft projects through donations. In addition to money, AMSAT makes creative use of leftover materials donated from aerospace industries worldwide.

AMSAT-NA has just one paid employee.

The rest of the organization, from the president to the workers designing and building space hardware, all donate their time and talents to the organization.

1.2 Amateur Satellites Today

The Amateur Radio satellites active when this edition of the *Handbook* went to press are shown in **Table 1**). All of these are low Earth orbiting (LEO) spacecraft that function either as communication relays or research platforms. Check **www.amsat.org/status/** for the latest information on active satellites.

Hams have been longing for a high-orbiting

"DX" satellite that would relay conversations across entire hemispheres. The last such satellite was OSCAR 40, which became silent in 2004. Unfortunately, it is becoming difficult for non-profit amateur satellite organizations to build such complex, powerful birds while relying solely on member dues and donations, not to mention thousands of hours

of volunteer labor. To make matters worse, launch opportunities for large satellites have become increasingly scarce and prohibitively expensive.

The German AMSAT organization, AMSAT-DL, is building a high-orbit satellite that is presently known as Phase 3 Express. This

satellite has yet to be launched. Both AMSAT-DL and AMSAT-NA are working on payloads which will be on satellites in geosynchronous orbits over different parts of the world.

For the foreseeable future, Amateur Radio satellite activity will likely be confined to spacecraft in low Earth orbits.

2 Satellite Transponders

In its most basic form, a *transponder* is the satellite communications system that receives signals from the Earth, alters their frequencies, amplifies them, and sends them back to Earth. The word originates from *transmitter* and *responder*. The transponder is at the heart of every satellite's ability to relay signals. There are three transponder types currently in use.

2.1 "Bent Pipe" Transponders

A bent-pipe transponder is the simplest transponder design in terms of function. It receives a signal at one frequency and simultaneously retransmits it at another. The metaphor is that of a U-shaped pipe that captures an object coming toward it and redirects the object back to its source (**Figure 1**).

A terrestrial FM repeater is a typical example of a bent-pipe transponder. Earthbound repeaters monitor one frequency and retransmit on another, usually (though not always) within the same band. Thanks to their elevated antenna systems, sensitive receivers and considerable output power, terrestrial repeaters can extend the coverage of mobile or hand-

held FM transceivers over hundreds or even thousands of square miles.

Bent-pipe satellite transponders also function as FM repeaters (although they could just as easily relay other modulation modes such as SSB). Satellite repeaters lack the output power of terrestrial repeaters because power generation in space is a difficult proposition. But what satellite repeaters lack in output power they more than make up for in antenna elevation. Even something as meager as a $\frac{1}{4}$ - $\frac{\lambda}{4}$ whip antenna can become a transmitting and receiving powerhouse when it is hundreds of miles above the planet.

The principle advantage of a bent-pipe transponder operating in the FM mode is that it is readily compatible with common Amateur Radio FM transceivers. Satellites such as SAUDI-OSCAR 50 (SO-50) and AMRAD-OSCAR 85 (AO-85) can be easily worked with the same transceivers you'd otherwise use to chat through a local FM repeater. It isn't uncommon to hear mobile and even handheld portable stations communicating through these satellites.

The principle *disadvantage* of a bent-pipe transponder is that it can relay only one signal

at a time. Multiple signals on the satellite uplink frequency interfere with each other, usually resulting in an unintelligible cacophony on the downlink. Thanks to the "capture effect" common to FM receivers, only the strongest signal will come through clearly. With only 10 or 15 minutes available during typical low-orbit passes, an inconsiderate operator running high power can use the capture effect to monopolize the satellite, effectively shutting out all other stations.

The solution to the bent-pipe problem is to have a satellite that can relay more than one signal at a time. That requires a completely different sort of transponder.

2.2 Linear Transponders

Unlike a bent-pipe transponder that can relay only one signal at a time, a linear transponder receives signals in a narrow slice of the RF spectrum (the *passband*), shifts the frequency of the passband, amplifies all signals linearly, and then retransmits everything back to Earth. Rather than relaying only one signal, a satellite equipped with a linear transponder can relay many signals at once (**Figure 2**).

From an operator point of view, linear transponders have an enormous advantage. With single-channel bent-pipe transponders, the user is obligated to finish a conversation quickly and clear the frequency so that someone else can make a contact. Not so with linear transponders. With the ample spectrum available through a linear transponder, there is more than enough "room" for everyone to communicate for as long as they please, or at least until the satellite travels out of range.

A linear transponder can be used with any type of signal when real time communication is desired. From the standpoint of conserving valuable spacecraft resources such as power and bandwidth, however, the preferred user modes are SSB and CW. Transponders are specified by first giving the approximate input frequency followed by the output frequency. For example, a 146/435-MHz transponder has an input passband centered near 146 MHz and an output passband centered near 435 MHz. The same transponder could be specified in wavelengths, as a 2 meter/70 cm unit.

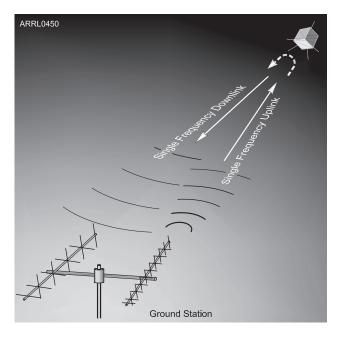

Figure 1 — A bent-pipe transponder gets its name from the way it functions. It takes the received uplink signal and instantly relays it on the downlink back to its source. Bent-pipe transponders are most often found on satellites that function primarily as FM repeaters.

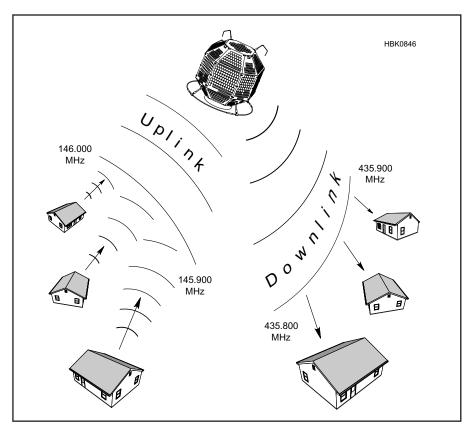

Figure 2 — Linear transponders repeat all signals received in an entire slice of spectrum. This allows the satellite to relay many conversations simultaneously.

TRANSPONDER MODES

To keep linear transponder specifications as simple as possible, the satellite community often uses so-called *Mode* designators. In the early years of amateur satellite operation, these designations were rather arbitrarily assigned and bore little resemblance to the actual frequencies in use. Fortunately, the am-

Table 2 Satellite Uplink/Downlink Mode **Designators**

Satellite Band Designations 10 m (29 MHz): H 2 m (145 MHz): V 70 cm (435 MHz): U 23 cm (1260 MHz): L 13 cm (2.4 GHz): S 5 cm (5.6 GHz): C 3 cm (10 GHz): X

Common Operating Modes (Uplink/Downlink) V/H (2 m/10 m)

H/V (10 m/2 m)

U/V (70 cm/2 m)

V/U (2 m/70 cm)

U/S (70 cm/13 cm)

U/L (70 cm/23 cm)

L/S (23 cm/13 cm)

L/X (23 cm/3 cm)

C/X (5 cm/3 cm)

ateur satellite community has since settled on a newer series of transponder specifications that are far more intuitive. For instance, in our previous example, the 2 meter band is tagged with the label "V" (for VHF) while the 70 cm band is labeled "U" (for UHF). Therefore, a transponder that listens on 2 meters and repeats on 70 cm is today usually called a Mode V/U transponder. See **Table 2**.

Transponder design is, in many respects, similar to receiver design. Input signals are typically on the order of 10^{-13} W and the output level can be up to several watts. A major difference, of course, is that the transponder output is at radio frequency while the receiver output is at audio frequency. A block diagram of a simple transponder is shown in

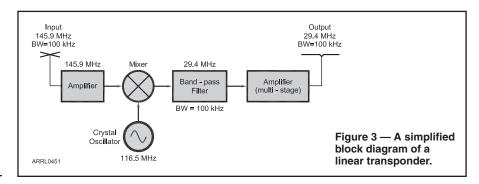

Figure 3. For several reasons, flight-model transponders are more complex than the one shown.

In spacecraft applications a key characteristic of a linear amplifier is its overall efficiency (RF output/dc input). Once we reach power levels above a few watts the use of class A, AB or B amplifiers cannot be tolerated. The power and bandwidth of a transponder must be compatible with each other and with the mission. That is, when the transponder is fully loaded with equal-strength signals, each signal should provide an adequate signal-tonoise ratio at the ground. Selecting appropriate values accurately on a theoretical basis using only link calculations is error prone. Experience with a number of satellites, however, has provided AMSAT with a great deal of empirical data from which it's possible to extrapolate accurately to different orbits, bandwidths, power levels, frequencies and antenna characteristics.

In general, low-altitude (300 to 1600 km) satellites that use passive magnetic stabilization and omnidirectional antennas can provide reasonable downlink performance with 1 to 10 W PEP at frequencies between 29 and 435 MHz, using a 50- to 100-kHzwide transponder. A high-altitude (35,000 km) spin-stabilized satellite that uses modest (7 to 10 dBi) gain antennas should be able to provide acceptable performance with 35 W PEP using a 300-kHz-wide transponder downlink at 146 or 435 MHz. Transponders are usually configured to be inverting in order to minimize Doppler shift. This means, for example, that a signal with a frequency at the low end of the uplink passband shifts to a corresponding point on the high end of the downlink passband. In the case of an SSB signal, the sideband modulation inverts as well—lower sideband on the uplink becomes upper sideband on the downlink.

DYNAMIC RANGE

The dynamic range problem for transponders is quite different from that for HF receivers. At first glance it may seem that the situation faced by satellite transponders is simpler. After all, an HF receiver must be

designed to handle input signals differing in strength by as much as 100 dB, while a lowaltitude satellite will encounter signals in its passband differing by perhaps 40 dB. Good HF receivers solve the problem by filtering out all but the desired signal before introducing significant gain. A satellite, however, has to accommodate all users simultaneously. The maximum overall gain can, therefore, be limited by the strongest signal in the passband.

Considering the state-of-the-art in transponder design and available spacecraft power budgets, an effective dynamic range of about 25 dB is about the most that can be currently obtained. In earlier satellites, the receiver AGC was normally adjusted to accommodate the loudest user. As a result, stations 25 dB weaker were not able to put a usable signal through the spacecraft even though they might be capable of doing so when the AGC is not activated. In the ideal situation users would adjust uplink power so that spacecraft AGC is never activated.

The "power-hog" problem is a serious one. A single station running excessive power can effectively swamp a linear transponder. Far too often, an inexperienced operator may believe that cranking up transmit power will improve downlink signal strength. Instead, that increase in power only serves to depress the downlink signal levels of all other stations.

In the short-lived OSCAR 40 satellite, the designers tried an innovative approach to the power-hog problem with the addition of LEILA (*LEI*stungs *L*imit *A*nzeige [Power Limit Indicator]). LEILA's computer continuously monitored the 10.7 MHz transponder IF passband. When an uplink signal exceeded a predetermined level, the computer inserted a CW message over the offender's downlink. The message indicated to the transmitting station that the transponder was being overloaded, and served as an inducement for the offending station to reduce power until the CW signal disappeared. If the overloading signal continued, or exceeded an even higher preset level, LEILA activated a notch filter tuned to the offending station's frequency. LEILA turned out to be highly effective. If you suddenly heard CW being transmitted over your signal on the downlink, you knew you had to reduce power immediately or face the consequences.

Since the transponder is the primary mission subsystem, reliability is extremely important. One way to improve system reliability is to include at least two transponders on

each spacecraft; if one fails, the other would be available full time. And there are significant advantages to *not* using identical units.

2.3 Digital Transponders

Digital transponders differ significantly from linear transponders. A digital transponder demodulates the incoming signal. The data can then be stored aboard the spacecraft (as in a packet mailbox) or used to immediately regenerate a digital downlink signal (as in a digipeater). Digipeating is most effective on high altitude spacecraft. Like linear transponders, digital units are downlink limited. A key step in the design procedure is to select modulation techniques and data rates to maximize the downlink capacity. Using assumptions about the type of traffic expected, the designers select appropriate uplink parameters. An analysis suggests that the uplink data capacity should be about four or five times that of the downlink because of "collisions" among signals trying to access the transponder.

For mailbox operation designers often use a PACSAT (packet radio satellite) model with similar data rates for the uplink and downlink, and they couple a single downlink with four uplinks. Fuji-OSCARs 12 and 20, and the MicroSat series ran both links at 1200 bps. These PACSATs contained an FM receiver with a demodulator that accepted Manchester-encoded FSK on the uplink. To produce an appropriate uplink signal, ground stations needed FM transmitters and packet radio modems known as terminal node controllers (TNCs) that were capable of generating the Manchester-encoded signal for the uplink.

The PACSAT downlink used binary phase-shift keying (BPSK) at an output of either 1.5 or 4 W. This modulation method was selected because, at a given power level and bit rate, it provides a significantly better bit error rate than other methods that were considered. One way of receiving the downlink is to use an SSB receiver and pass the audio output to a PSK demodulator. The SSB receiver is just serving as a linear downconverter in this situation. Other methods of capturing the downlink are possible but the two proven systems now operating use this approach.

During the heydays of the PACSATs, there were several TNCs designed specifically for this application. Over time the PACSATs have gradually gone out of service and those specialized TNCs have all but disappeared

from the marketplace. The remaining digital satellite transponders use 1200 bps AFSK or 9600 bps FSK data transmissions for both uplink and downlink. This means that ordinary packet radio TNCs—the kind currently used for various terrestrial applications—can be used with these digital satellites as well. Software has been able to take the place of standalone TNCs so that a simpler interface between the computer's sound hardware and the transceiver may be the only required hardware.

RUDAK

A discussion of digital transponders would not be complete without mentioning RU-DAK. RUDAK is an acronym for Regenerativer Umsetzer fur Digitale Amateurfunk Kommunikation (Regenerative Transponder for Digital Amateur Communications). Early RUDAK systems took a different approach to achieving the desired ratio of uplink to downlink capacity. The one flown on OSCAR 13 used one uplink channel and one downlink channel with the data rate on the uplink (2400 bps) roughly six times that on the downlink (400 bps). The 400 bps rate on the downlink was chosen because this was the standard that had been used for downlinking high-orbiting satellite telemetry since the late 1970s. Users already capturing telemetry would be able to capture RUDAK transmissions from day one. Unfortunately, the RUDAK unit on OSCAR 13 failed during launch.

A system known as RUDAK II was flown on RS-14/AO-21 and actually consisted of two units. One unit was similar to the RUDAK flown on OSCAR 13. However, the other unit, known as the RUDAK Technology Experiment (or RTX), was a new experimental transponder using DSP technology. It was essentially a flying test bed for ideas being considered for future high-orbit missions.

The RUDAK-U system flown on OSCAR 40 contained two CPUs, one 153.6 KB modem, four hardwired 9600 baud modems and eight DSP modems capable of operating at speeds up to 56 KB. The great advantages of modern RUDAK systems are their extraordinary flexibility. Through the use of digital signal processing, the RUDAK is able to configure itself into any type of digital system desired. Had OSCAR 40 survived, the plan was to use its RUDAK system to create a highly capable digital communications platform in space.

3 Satellite Tracking

3.1 Satellite Orbits

Most active amateur satellites are in various types of low Earth orbits (LEOs) at altitudes that vary between approximately 350 km (the International Space Station) and 1450 km (OSCAR 7). There are satellites planned for future launch that will travel in the high Earth

orbits (HEOs). At their closest approaches to Earth (their *perigees*), these satellites may come within 1000 km; at the highest points of their orbits (their *apogees*), they will travel as far as 50,000 km into space. Let's take a brief look at several of the most common orbits.

An inclined orbit is one that is inclined

with respect to the Earth's equator. See **Figure 4A**. A satellite that is inclined 90° would be orbiting from pole to pole; smaller inclination angles mean that the satellite is spending more time at lower latitudes. The International Space Station, for example, travels in an orbit that is inclined about 50° to the equator.

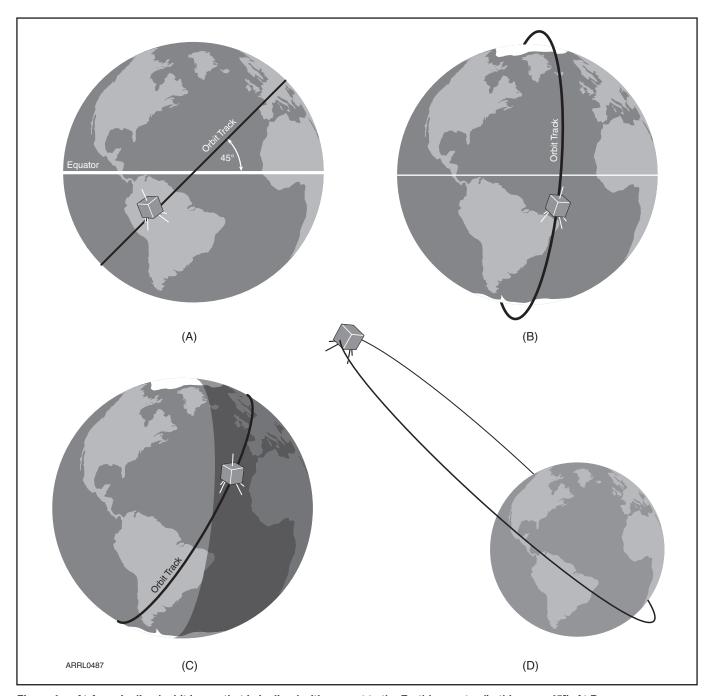

Figure 4 — At A, an *inclined* orbit is one that is inclined with respect to the Earth's equator (in this case, 45°). At B, a *sun-synchronous* orbit takes the satellite over the north and south poles, allowing every station in the world to enjoy at least one high-elevation pass per day. At C, a *dawn-to-dusk* orbit is a variation on the sun-synchronous model except that the satellite spends most of its time in sunlight and relatively little time in eclipse. At D, the *Molniya* orbit is an elliptical orbit that carries the satellite far into space at its greatest distance from Earth (apogee). To observers on the ground, the satellite at apogee appears to hover for hours at a time before it plunges earthward and (often) sweeps within 1000 km at its closest approach (perigee).

Satellites that move in these orbits frequently fall into the Earth's shadow (eclipse), so they must rely on battery systems to provide power when the solar panels are not illuminated. Depending on the inclination angle, some locations on the Earth will never have good access because the satellites will rarely rise above their local horizons. This was true, for example, in the days when the US Space Shuttles carried Amateur Radio operators. Shuttle orbits were usually inclined at low angles, which meant that Shuttles barely made it above the horizon for hams in the northern US and Canada.

A *sun-synchronous* orbit takes a satellite over the north and south poles. See Figure 4B. There are two advantages to a sun-synchronous orbit: (1) the satellite is available at approximately the same time of day, every day and (2) everyone, no matter where they are, will enjoy at least one high-altitude pass per day. OSCAR 29 is a good example of a satellite that travels in a sun-synchronous orbit.

A *dawn-to-dusk* orbit is a variation on the sun-synchronous model except that the satellite spends most of its time in sunlight and relatively little time in shadow.

The *Molniya* high Earth orbit (Figure 4D) was pioneered by the former Soviet Union. It is an elliptical orbit that carries the satellite far into space at its greatest distance from Earth. To observers on the ground, the satellite at apogee appears to hover for hours at a time before it plunges earthward and sweeps around the Earth at its closest approach. One great advantage of the Molniya orbit is that the satellite is capable of "seeing" an entire hemisphere of the planet while at apogee. Hams can use a Molniya satellite to enjoy long, leisurely conversations spanning thousands of kilometers here on Earth. When this book was written, however, there were no active ham satellites traveling in Molniya orbits.

3.2 Satellite Tracking Software

The key to communicating through a satellite is being able to track its movements and predict when it will appear above your local horizon. Fortunately, we have sophisticated software available that streamlines this task considerably.

You'll find satellite-tracking software written for *Windows*, *MacOS* and *Linux* operating systems. Several popular applications are listed in **Table 3**. When computers were first employed to track amateur satellites, they provided only the most basic, essential information: when the satellite will be available (*AOS*, acquisition of signal), how high the satellite will rise in the sky and when the satellite is due to set below your horizon (*LOS*, loss of signal). Today we tend to ask a great deal more of our tracking programs. Modern applications still provide the basic information, but they usually offer many more features such as:

- The spacecraft's operating schedule, including which transponders and beacons are on
- Predicted frequency offset (Doppler shift) on the link frequencies.
- The orientation of the spacecraft's antennas with respect to your ground station and the distance between your ground station and the satellite.
- Which regions of the Earth have access to the spacecraft; that is, who's in QSO range?
- Whether the satellite is in sunlight or being eclipsed by the Earth. Some spacecraft only operate when in sunlight.
- When the next opportunity to cover a selected terrestrial path (mutual window) will occur.
- Changing data can often be updated at various intervals such as once per minute or even once per second.

A number of applications do even more. Some will control antenna rotators, automatically keeping directional antennas aimed at the target satellite. Other applications will also control the radio to automatically compensate for frequency changes caused by Doppler shifting.

Adding additional spacecraft to the scenario suggests more questions. Which satellites are currently in range? How long each will be accessible? Will any new spacecraft be com-

ing into range in the near future? Obviously there is a great deal of information of potential interest. Programmers developing tracking software often find that the real challenge is not solving the underlying physics problems, but deciding what information to include and how to present it in a useful format. This is especially true since users have different interests, levels of expertise and needs. Some prefer to see the information in a graphical format, such as a map showing real-time positions for all satellites of interest. Others may prefer tabular data such as a listing of the times a particular spacecraft will be in range over the next several days.

There are also several Internet sites where you can do your tracking online. This eliminates all the hassles associated with acquiring and installing software. The currently available online tracking sites are not as powerful or flexible as the software you can install on your PC, however. One interesting site of this type is maintained by AMSAT-NA and you'll find it at www.amsat.org/amsat-new/tools/predict. A couple of other useful sites include www.celestrak.com and www.n2yo.com.

3.3 Getting Started With Software

There are so many different types of satellite software, and they change so frequently, it would be foolhardy to attempt to give you detailed operational descriptions in any book. The book would be obsolete a month after it came off the press!

Even so, there are a number of aspects of satellite-tracking software that rarely change. For instance, most programs will ask you to enter your station location as part of the initial setup process. Some applications use the term "observer" to mean "station location," but the terms are synonymous for the sake of our discussion. Sophisticated programs will go as far as to provide you with a list of cities that you can select to quickly enter your location. Other programs will ask you to enter your latitude and longitude coordinates manually.

When entering latitude, longitude (and oth-

Table 3 A Sampling of Satellite Tracking Software

Name	Source	Operating	Radio	Antenna
		System	Control?	Control?
SatPC32	www.dk1tb.de (free trial)			
	www.amsat.org (store, for license keys)	Windows	Yes	Yes
MacDoppler	www.dogparksoftware.com/MacDoppler.html	Mac OS	Yes	Yes
Ham Radio Deluxe	www.hamradiodeluxe.com	Windows	Yes	No
Gpredict	gpredict.oz9aec.net	Win/Mac/Linux	Yes	Yes

Many apps are also available for mobile operating systems such as Android, iOS, BlackBerry, and Windows Phone. Search the appropriate store for "satellite tracking" or "AMSAT tracking" for options on your operating system.

er angles), make sure you know whether the computer expects degree-minute or decimal-degree notation. Following the notation used by the on-screen prompt usually works. Also make sure you understand the units and sign conventions being used. For example, longitudes may be specified as negative values for locations west of Greenwich (0° longitude). Latitudes in the southern hemisphere may also require a minus sign. Fractional parts of a degree will have very little effect on tracking data so in most cases you can just ignore it.

Dates can also cause considerable trouble. Does the day or month appear first? Can November be abbreviated Nov or must you enter 11? The number is almost always required. Must you write 2010 or will 10 suffice? Should the parts be separated by colons, dashes or slashes? The list goes on and on. Once again, the prompt is your most important clue. For example, if the prompt reads "Enter date (DD:MM:YY)" and you want to enter February 9, 2010 follow the format of the prompt as precisely as possible and write 09:02:10.

When entering numbers, commas should never be used. For example, if a semi-major axis of 20,243.51 km must be entered, type 20243.51 with the comma and units omitted. It takes a little time to get used to the quirks of each software package, but you'll soon find yourself responding automatically.

Once you have your coordinates entered, you're still not quite done. The software now "knows" its location, but it doesn't know the locations of the satellites you wish to track. The only way the software can calculate the positions of satellites is if it has a recent set of *orbital elements*.

3.4 Orbital Elements

Orbital elements are sets of six numbers that completely describe the orbit of a satellite at a specific time. Although scientists may occasionally use different groups of six quantities, radio amateurs nearly always use the six known as Keplerian Orbital Elements, or simply *Keps*.

These orbital elements are derived from very precise observations of each satellite's orbital motion. Using precision radar and highly sensitive optical observation techniques, the North American Aerospace Defense Command (NORAD) keeps a very accurate catalog of almost everything in Earth orbit. Periodically, they issue the unclassified portions of this information for release to the general public. The information is listed by individual catalog number of each satellite and contains numeric data that describes, in a mathematical way, how NORAD observed the satellite moving around the Earth at a very precise location in space at a very precise moment in the past.

Table 4

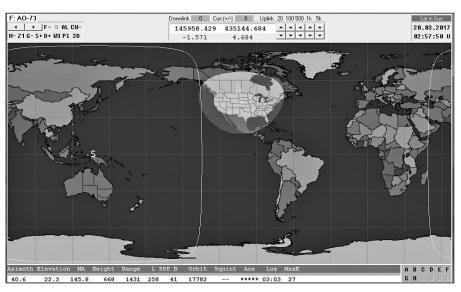

Figure 5 — This image shows the circular footprint of OSCAR 73 as depicted by *SatPC32* satellite-tracking software. The footprint indicates the area of the Earth that is visible to the satellite at any given time.

Without getting into the complex details of orbital mechanics, suffice it to say that your software simply uses the orbital element information NORAD publishes that describe where a particular satellite was "then" to solve the orbital math and make a prediction (either graphically or in tabular format) of where that satellite ought to be "now." The "now" part of the prediction is based on the local time and station location information you've also been asked to load into your software.

Orbital elements are frequently distributed with additional numerical data (which may or may not be used by a software tracking program) and are available as NASA Two-Line Elements (see **Table 4** for an example). Satellite tracking programs read these elements and use them to generate predictions. One method of entering orbital elements is to grab the latest set from the AMSAT-NA website at www.amsat.org (look under "Keplerian Elements Resources" in the Satellite Info menu). You can download the element set as a text file and then tell your satellitetracking program to read the file and create the database. Another excellent site is CelesTrak at celestrak.com.

If you're fortunate to own sophisticated tracking software such as *SatPC32* or *Mac*-

Doppler, and you have access to the Internet, the program will reach into cyberspace, download and process the Keps automatically. All it takes is a single click of your mouse button. Some programs can even be configured to download the latest Keps on a regular basis without any prompting from you.

3.5 Other Tracking Considerations

SATELLITE FOOTPRINTS

Many satellite tracking applications display not only the satellite track, but also the satellite footprint. A satellite footprint can be loosely defined as the area on the Earth's surface that is "illuminated" by the satellite's antenna systems at any given time. Another way to think of a footprint is to regard it as the zone within which stations can communicate with each other through the satellite.

Unless the satellite in question is *geostationary*, footprints are constantly moving. Their sizes can vary considerably, depending on the altitude of the satellite. The footprint of the low-orbiting International Space Station is approximately 4100 km in diameter. In contrast, the higher orbiting OSCAR 7 has

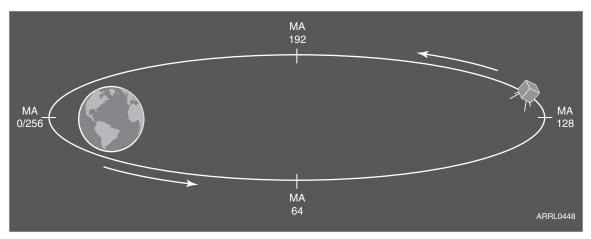

Figure 6 — Mean anomaly (MA) divides each orbit into 256 segments of equal time duration. Radio amateurs refer to these as "Mean Anomaly" or "Phase" units. The duration of each segment is the satellite's period divided by 256. For example, a mean anomaly unit for OSCAR 13 was roughly 2.68 minutes. At MA 0 (beginning of orbit) and MA 256 (end of orbit) the satellite is at perigee (its lowest point). At MA 128 (halfway through the orbit) the satellite is at apogee (or its highest point).

a footprint that is over 8000 km across. See the example of a satellite footprint in **Figure 5**. The amount of time you have available to communicate depends on how long your station remains within the footprint. This time can be measured in minutes, or in the case of a satellite in a highly elliptical orbit, hours.

It is worthwhile to note that the size and even the shape of a footprint can also vary according to the type of antenna the satellite is using. A highly directional antenna with a narrow beamwidth will create a small footprint even though the satellite is traveling in a high-altitude orbit. This usually isn't an issue for amateur satellites, however.

A SATELLITE'S "PHASE"

Some satellites use operating schedules to determine which transponders and antennas are active at any given time. It is based on the *phase* of the satellite's *mean anomaly*, or *MA*. Many software applications can use this information to provide detailed predictions that tell you not only when the satellite will appear, but also which transponders will be active at the time.

The expression "anomaly" is just a fancy term for angle. Astronomers have traditionally divided orbits into 360 mean-anomaly units, each containing an equal time segment. Because of the architecture of common microprocessors, it was much more efficient to design the computers controlling spacecraft to divide each orbit into 256 segments of equal time duration. Radio amateurs refer to these as mean anomaly or phase units. The duration of each segment is the satellites period divided by 256. For example, a mean anomaly unit for OSCAR 13 was roughly 2.68 minutes. At MA 0 (beginning of orbit) and MA 256 (end of orbit) the satellite is at perigee (its lowest point). At MA 128 (halfway through

the orbit) the satellite is at apogee or high point. See **Figure 6**.

Because radio amateurs and astronomers use the term mean anomaly in a slightly different way, there's sometimes a question as to which system is being used. Any confusion is minor and usually easily resolved. Most OSCAR telemetry with real-time MA values and schedules use the 256 system. The term "phase," and the fact that no numbers larger than 256 ever appear, are significant hints.

Computer tracking programs designed for non-radio amateur audiences generally use the traditional astronomical notation. It's easy to determine when this is the case because the mean anomaly column will contain entries between 257 and 360.

If a satellite is using an MA-based transponder schedule, the schedule will be posted on the AMSAT-NA website at **www.amsat. org**. (When this book was written there were no Amateur Radio satellites in orbit using MA

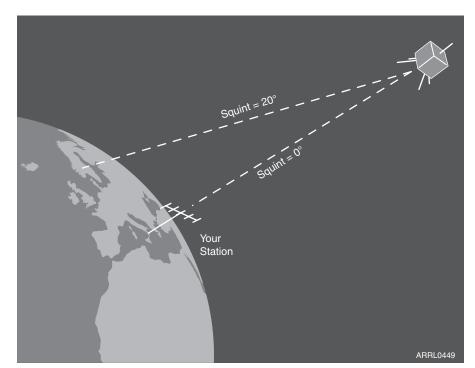

Figure 7 — The squint angle describes how the directive antennas on a satellite (such as Phase 3 satellites) are pointed with respect to your ground station. Squint angles can vary between 0° and 180°. A squint angle of 0° means the satellite antennas are pointed directly at you, which, in turn, means good link performance can usually be expected. When the squint angle is above 20° signal level begins to drop.

scheduling, but this may change as currently planned satellites reach orbit.) Depending on its sophistication, your tracking software may allow you to enter this schedule data.

SQUINT ANGLE

Another dilemma your software may help resolve is the *squint angle*. The squint angle describes how the directive antennas on a satellite are pointed with respect to your ground station. Squint angle can vary between 0° and 180°. A squint angle of 0° means the satellite antennas are pointed directly at you and that generally indicates that good link performance can be expected (**Figure 7**). When the squint angle is above 20°, signal level begins to drop and a disruptive amplitude

flutter called spin modulation on uplinks and downlinks may become apparent.

Programs that include algorithms to calculate squint angle require information about the orientation or attitude of the satellite. This information is generally available from sources that provide the basic orbital elements and on telemetry sent directly from the satellite of interest. The parameters needed are labeled Bahn latitude and Bahn longitude. They are also known as BLAT and BLON or ALAT and ALON where the prefix "A" stands for attitude.

Programs that provide squint angle information may also contain a column labeled *Predicted Signal Level*. Values are usually computed using a simple prediction model

that takes into account satellite antenna pattern, squint angle and spacecraft range. The model assumes a 0 dB reference point with the satellite overhead, at apogee and pointing directly at you. At any point on the orbit the predicted level may be several dB above (+) or below (–) this reference level.

You won't need to be concerned about squint angle for most LEO satellites. It only becomes a factor with the high-orbit birds since they generally use directive antennas. As with MA scheduling, you'll want to know that the satellite's antennas are pointing at your location before you fire up your equipment. With the right kind of software, you'll know well ahead of time.

4 Satellite Ground Station Antennas

Assembling a satellite ground station presents a different challenge compared to typical HF station setups. There are a number of variables that change depending on the types of satellites you hope to use. A ground station designed strictly for LEO satellites differs substantially from one intended for HEO birds. There are also issues surrounding computers and software, particularly if you plan to access digital satellites.

One aspect of your ground station with the greatest range of choice is your antenna system. To use most amateur satellites, you must transmit on one band (the uplink) and receive on another band (the downlink). Unless you are using a single, dual-band antenna, your satellite station will require at least two antennas. Some satellite operators have several antennas so that they can operate on various uplink/downlink band combinations as the need arises.

Figure 8 — A circularly polarized wave front describes a rotational path about its central axis, either clockwise (right-hand or RHCP) or counter clockwise (left-hand or LHCP).

4.1 Antenna Polarization

The *polarization* of a satellite antenna is an important factor, regardless of whether it is used for transmitting or receiving. Polarization is determined by the position of the radiating element or wire with respect to the Earth. A radiator that is parallel to the Earth radiates horizontally, while a vertical radiator radiates a vertical wave. These are so-called *linearly polarized* antennas. If the radiating element is slanted above the Earth, it radiates waves that have *both* vertical and horizontal components.

For terrestrial VHF+line-of-sight communication, polarization matching is important. If one station is using a horizontally polarized antenna and the other is using a vertically polarized antenna, the mismatch can result in a large signal loss under certain conditions. We don't worry about polarization mismatches on HF frequencies because whenever signals are refracted through the ionosphere, which frequently happens to HF signals, polarization changes anyway.

The problem with applying polarization concerns to spacecraft is that the orientation of a satellite's antennas relative to your ground station is constantly changing. This often results in fading when the polarization of its antennas conflict with yours. This problem doesn't plague satellites exclusively. Aircraft, automobiles and all other moving radio platforms can suffer the same effects.

Fortunately, there is a "cure" known as *circular polarization* (CP). With CP, wave fronts appear to rotate as they pass the receiving sta-

tion, either clockwise (right-hand or RHCP) or counter clockwise (left-hand or LHCP). See **Figure 8**. The advantage of using circular polarization is that it can substantially reduce the effects of polarization conflict. Since the polarization of a CP antenna rotates through horizontal and vertical planes, the resulting pattern effectively "smoothes" the fading effects, generating consistent signals as a result.

That said, your satellite ground station antennas do *not* need to be circularly polarized to be effective. Linearly polarized antennas, either horizontal or vertical, are perfectly useful. Some ground station antenna designs use slanted or "crossed" elements to mix the horizontal and vertical polarization components as discussed earlier. The goal of fine-tuning your antenna polarization is to

give your station an edge, something that is important when you are dealing with weak signals from deep space. But, while circular polarization of your antennas may give your station a definite advantage, it isn't an absolute requirement.

4.2 Omnidirectional Antennas

An ideal omnidirectional antenna radiates and receives signals in all directions equally. In the real world, most "omnidirectional" antennas have a certain amount of directivity. For example, a common ground plane antenna (**Figure 9**) is considered to be omnidirectional, but as you can see in **Figure 10** the radiation pattern is not uniform. Notice the deep null directly overhead. Signals will fade sharply as satellites move through this null, particularly during high-elevation passes.

Despite their low gain, omnidirectional antennas are attractive because they do not need to be aimed at their targets. This means that they don't require mechanical antenna rotators, which can add significant cost and complexity to a ground station. Omni antennas are also more compact than directional antennas for the same frequency. On the other hand, their low gain makes them practical only for LEO satellites that have sensitive receivers and relatively strong transmit signals.

Technically speaking, any type of omnidirectional antenna can be used for a satellite ground station. Hams have enjoyed satellite operations with simple ground planes, J-poles, "big wheels" and even automobile antennas. But for best results with an omnibased antenna system, you'll want a radiation pattern that minimizes the polarization conflicts and pattern nulls that can cause signals to fade. To this end, engineers have designed a number of omnidirectional antennas with these issues in mind.

THE EGGBEATER

The *eggbeater* antenna is a popular design named after the old-fashioned kitchen utensil it resembles (**Figure 11**). The antenna is com-

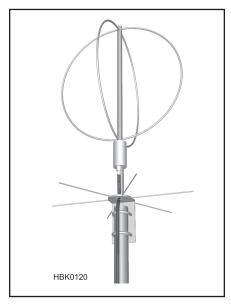

Figure 11 — The eggbeater antenna is a popular design named after the old-fashioned kitchen utensil it resembles. The antenna is composed of two full-wave loops of rigid wire or metal tubing.

posed of two full-wave loops of rigid wire or metal tubing. Each of the two loops has an impedance of 100 Ω , and when coupled in parallel they offer 50 Ω impedance, matching coaxial feed lines. The loops are fed 90° out of phase with each other and this creates a circularly polarized pattern.

An eggbeater may also use one or more parasitic reflector elements beneath the loops to focus more of the radiation pattern upward. This effect makes it a "gain" antenna, but that gain is at the expense of low-elevation reception. Toward the horizon an eggbeater is actually horizontally polarized. As the pattern rises in elevation, it becomes more and more right-hand circularly polarized. Experience has shown that eggbeaters seem to perform best when reflector elements are installed just below the loops.

Eggbeaters can be built relatively easily, but there are also a couple of commercial models available (see the advertising pages of *QST* magazine). The spherical shape of the eggbeater creates a fairly compact antenna when space is an issue, which is another reason why it is an attractive design.

THE TURNSTILE

The basic *turnstile* antenna consists of two horizontal half-wave dipoles mounted at right angles to each other (like the letter "X") in the same horizontal plane with a reflector screen beneath (**Figure 12**). When these two antennas are excited with equal currents 90° out of phase, their typical figure-eight patterns merge to produce a nearly circular pattern.

In order to get the radiation pattern in the upward direction for space communications, the turnstile antenna needs a reflector underneath. For a broad pattern it is best to maintain a distance of $\frac{3}{2}$ λ at the operating frequency

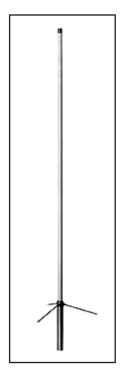

Figure 9 — An ordinary ground plane antenna. This particular model is designed for terrestrial communications on 2 m.

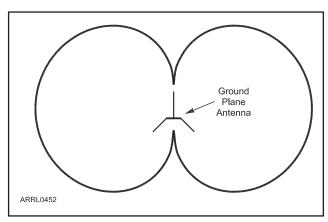

Figure 10 — The simplified radiation pattern of a ground plane antenna. Notice the deep null directly overhead.

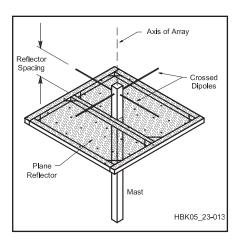

Figure 12 — The basic turnstile antenna consists of two horizontal half-wave dipoles mounted at right angles to each other (like the letter "X") in the same horizontal plane with a reflector screen beneath.

between the reflector and the turnstile. Homebrewed turnstile reflectors often use metal window-screen material that you can pick up at many hardware stores. (Make sure it is a metal, not plastic, screen material.)

Like their cousins the eggbeaters, turnstiles are relatively easy to build. In fact, building one may be your only choice since turnstiles are rarely available off the shelf.

THE LINDENBLAD ANTENNA

In a Lindenblad antenna (Figure 13), each dipole element is attached to a section of shorted open-wire-line, also made from tubing, which serves as a balun transformer. A coaxial cable runs through one side of each open-wire line to feed each dipole. The four coaxial feed cables meet at a center hub section where they are connected in parallel to provide a four-way, in-phase power-splitting function. This cable junction is connected to another section of coaxial cable that serves as an impedance matching section to get a good match to 50Ω . An innovative solution, the EZ-Lindenblad, is described later in this chapter. While certainly more elaborate than an eggbeater or turnstile, the Lindenblad creates a uniform circularly polarized pattern that is highly effective for satellite applications.

THE QUADRIFILAR HELICOIDAL ANTENNA

The quadrifilar helicoidal antenna (QHA) shown in **Figure 14** ranks among the best of the omnidirectional satellite antennas. It is comprised of four equal-length conductors (filars) wound in the form of a corkscrew

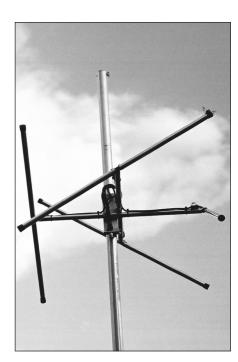

Figure 13 — The EZ Lindenblad antenna designed by Anthony Monteiro, AA2TX.

(helix) and fed in quadrature. The result is a nearly perfect circularly polarized pattern.

QHAs can be challenging to build since the filar lengths and spacing have to be precise. Even so, homebrewing a QHA can save you a substantial amount of money. This antenna is available off the shelf (they are favorites for maritime satellite links), but they can be costly. A version that can be built from readily available materials is described later in this chapter.

4.3 Directional Antennas

Gain and directivity are important antenna factors. These factors are maximized in *directional* antennas. In fact, the design goal of a directional antenna is to create a highly directional pattern along its axis (**Figure 15**). An ordinary flashlight is a reasonable analog for a directional antenna, although the pattern of a directional antenna isn't as well focused as a flashlight beam (antennas with parabolic reflectors come fairly close, though).

The chief advantage of a directional antenna is its considerable directivity and gain. When you are working with weak signals from spacecraft, you need all the gain you can get. Directional antennas are mandatory for high-altitude satellites when they are at apogee, nearly 50,000 km distant. They also

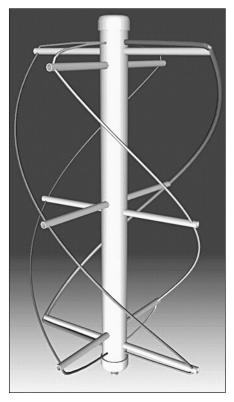

Figure 14 — The quadrifilar helicoidal antenna is comprised of four equal-length conductors (filars) wound in the form of a corkscrew (helix) and fed in quadrature.

are excellent for LEO birds, providing strong, consistent signals that omnidirectional antennas can rarely match.

But, a major disadvantage of a directional antenna is *also* its directivity! To achieve best results with a directional antenna, you must find a way to point it at the satellite you wish to work. This entails pointing it by hand, or by using an antenna rotator. If you were to simply leave a directional antenna fixed in one place, you would enjoy good signals only during the brief moments when satellites passed through the antenna's pattern. A rotator adds significant cost to a ground station and installing one isn't a trivial exercise. On the other hand, there is a way to reduce rotator cost, which we'll discuss later.

If you can afford a directional antenna and rotator system, you'll never regret the investment. When properly installed, it is vastly superior to any omnidirectional antenna you are likely to encounter.

YAGI ANTENNAS

The familiar Yagi antennas used for VHF+ terrestrial operation can be used for satellite applications as well. However, keep in mind that the greater the directivity, the more focused (narrow) the antenna pattern. This translates to an antenna that must be aimed at a satellite with a fair degree of accuracy. This can be a challenge when your target is a rapidly moving LEO bird.

The Yagi antennas you normally see are *linear* designs that are mounted in either horizontal or vertically polarized configurations. These same antennas can be successfully used for satellite work just as they are. However, there are ways you can optimize them to increase their effective performance.

The dipole elements of Yagi antennas radiate linearly polarized signals, but remember

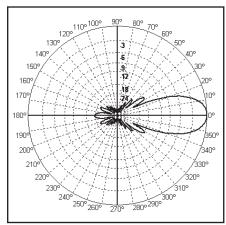

Figure 15 — The design goal of a directional antenna is to create a highly directional pattern along its axis. This example shows the radiation pattern of a high-gain Yagi antenna.

that the polarization direction really depends on the orientation of the antenna to the Earth. If two Yagi antennas are mounted on the same support boom, arranged for horizontal and vertical polarization, and combined with the correct phase difference (90°), a circularly polarized wave results. Because the electric fields of the antennas are identical in magnitude, the power from the transmitter will be equally divided between the two fields. Another way of looking at this is to consider the power as being divided between the two antennas; hence the gain of each is decreased by 3 dB when taken alone in the plane of its orientation. This design is known as a crossed Yagi.

A 90° phase shift must exist between the two antennas and the simplest way to obtain this shift is to use two feed lines. One feedline section is $\frac{1}{4}$ - λ longer than the other, as shown in Figure 16. These separate feed lines are then paralleled to a common transmission line to the station. However, therein lies one of the headaches of this system. Assuming negligible coupling between the crossed antennas, the impedance presented to the common transmission line by the parallel combination is one half that of either section alone. (This is not true when there is mutual coupling between the antennas, as in phased arrays.) Figure 17 shows a practical example of offset crossed Yagis for the 23 cm band.

So far we've been discussing single-band crossed Yagi designs to achieve circular-polarization, or something close to it. If circular polarization isn't a top criterion, you may want to consider a dual-band Yagi that places linear Yagi antennas for two separate bands on the same support boom. While this design doesn't produce circular polarization, it partially makes up for that disadvantage in convenience and economics. The most common design combines antennas for 2 meters and 70 cm on the same boom (Figure 18). You can feed the antennas with two separate feed lines, or use single feed line and a diplexer (some manufacturers incorrectly call them duplexers) to separate the signals at the antenna, at the radio or at both locations (Figure 19). With a single 2 meter/70 cm Yagi antenna you can enjoy nearly all available amateur satellites. That single-purchase aspect makes them attractive for budget-conscious hams.

A type of Yagi that you may encounter for higher frequencies (typically 902 MHz and above) is the *loop Yagi* (Figure 20). In this design, the individual elements are bent into loops and mounted on a common boom. Despite their appearance, loop Yagis are linearly polarized antennas. Their advantage is that they create a substantial amount of gain in a relatively small physical space. Because of the sizes of the loops, however, loop Yagis are most practical and common at microwave frequencies.

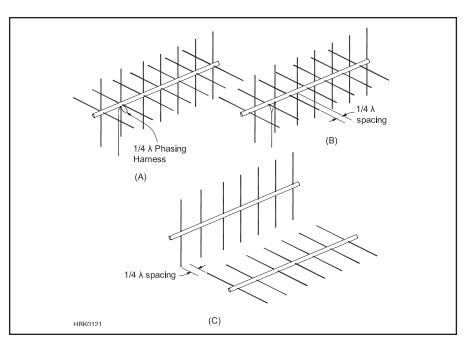

Figure 16 — Evolution of the circularly polarized Yagi. The simplest form of crossed Yagi, A, is made to radiate circularly by feeding the two driven elements 90° out of phase. Antenna B has the driven elements fed in phase, but has the elements of one bay mounted $\frac{1}{4}\lambda$ forward from those of the other. Antenna C offers elliptical (circular) polarization using separate booms. The elements in one set are mounted perpendicular to those of the other and are spaced $\frac{1}{4}\lambda$ forward from those of the other.

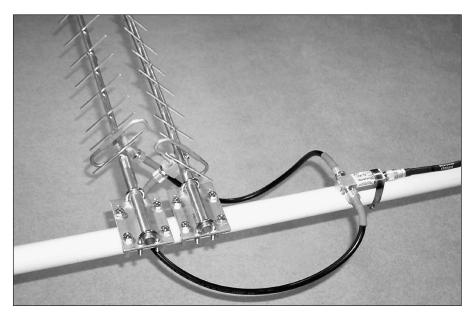

Figure 17 — An example of offset crossed-Yagi circularly polarized antennas with fixed polarization. This example shows a pair of Yagis for L band (1296 MHz) mounted on an elevation boom. [KD1K photo]

HELICAL ANTENNAS

Another method to create a circularly polarized signal is by means of a helical antenna. The axial-mode helical antenna was introduced by Dr John Kraus, W8JK, in the 1940s. **Figure 21** shows an example of a microwave helical antenna. A larger helical antenna for

70 cm is shown in Figure 22.

This antenna has two characteristics that make it especially interesting and useful for satellite stations. First, the helix is circularly polarized. As discussed earlier, circular polarization is simply linear polarization that continually rotates as it travels through space. In the case of a helical antenna, this rotation

Figure 18 — Joe Bottiglieri, AA1GW, uses a dual-band Yagi to work a low-Earth orbiting FM repeater satellite with a handheld transceiver.

Figure 19 — A diplexer made by the Comet Corporation. Diplexers can be used to separate or combine signals on different bands.

is about the axis of the antenna. This can be pictured as the second hand of a watch moving at the same rate as the applied frequency, where the position of the second hand can be thought of as the instantaneous polarization of the signal. The second interesting property of the helical antenna is its predictable pattern, gain and impedance characteristics over a wide frequency range. This is one of

the few antenna designs that have both broad bandwidth and high gain. The benefit of this property is that, when used for narrow-band applications, the helical antenna is very forgiving of mechanical inaccuracies.

Electrically, a helix looks like a large airwound coil with one of its ends fed against a ground plane. The ground plane often consists of a screen of 0.8 to 1.1λ diameter (or per

side for a square ground plane). The circumference of the coil form must be between 0.75 and 1.33 λ for the antenna to radiate in the axial mode. The coil should have at least three turns to radiate in this mode. The ratio of the spacing between turns should be in the range of 0.2126 to 0.2867 λ . The winding of the helix comes away from the cupped reflector with a counterclockwise winding direction for LHCP. A clockwise winding direction yields RHCP.

PARABOLIC DISH ANTENNAS

A number of modern ham satellites have included microwave transponders and some will do so again in the near future. This has created a great deal of interest in effective microwave antennas. From the ground station "point of view," antennas for the microwave bands are not only small, they pack a high amount of gain into their compact packages. Among the best high-performance antenna designs for microwave use are those that em-

ploy parabolic reflectors (so-called parabolic "dishes") to concentrate the transmitted and received energy.

Like a bulb in a flashlight, a parabolic antenna must have a *feed source*—the radiating and receiving part of the antenna—"looking" into the surface of the dish. Some dishes are designed so that the feed source is mounted directly in front of the dish. This is referred

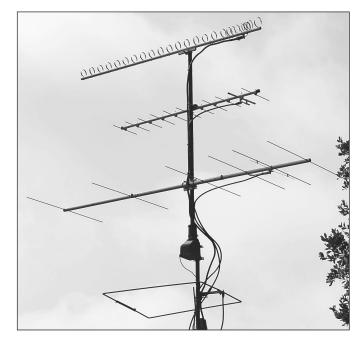

Figure 20 — This antenna stack includes a loop Yagi at the very top.

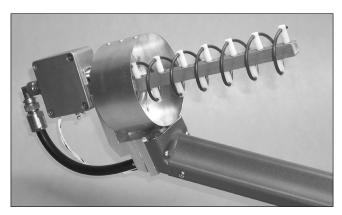

Figure 21 — A seven-turn LHCP helical antenna for a 2.4 GHz dish feed. This helical antenna uses a cupped reflector and has a preamplifier mounted directly to the antenna feed point. [Dick Jansson, KD1K, photo]

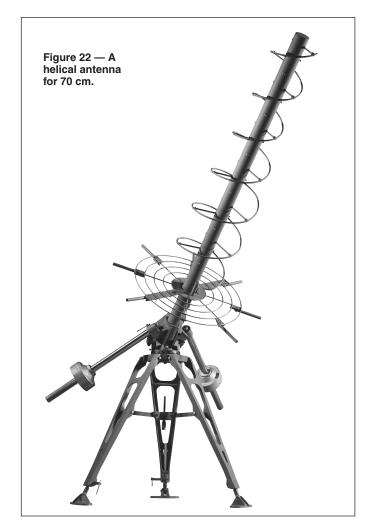

Figure 23 — As you can see, the feed source is directly in front, making this a center-fed dish.

Figure 24 — This is a good example of an offset-fed dish. Note the feed source at the bottom edge of the photo, pointing into the center of the parabola. Also note that this is a DirectTV satellite TV antenna that has been "repurposed" for Amateur Radio satellites!

to as a *center-fed dish* (**Figure 23**). Other dishes are designed so that the feed source is off to one side, referred to as an *off-center-fed dish*, or just offset fed dish, as shown in **Figure 24**. The offset-fed dish may be considered a side section of a center-fed dish. The center-fed dish experiences some signal degradation due to blockage by the feed system, but this is usually an insignificantly small amount. The offset-fed dish is initially more difficult to aim, since the direction of reception is not the center axis, as it is for center-fed dishes.

The dish's parabola can be designed so the focus point—the point where the feed source must be—is closer to the surface of the dish, referred to a short-focal-length dish, or further away from the dish's surface, referred to as a long-focal-length dish. To determine the exact focal length (F), measure the diameter of the dish (D) and the depth of the dish (d).

$F = D^2 / 16d$

The focal length divided by the diameter of the dish gives the *focal ratio*, commonly shown as f/D. Center-fed dishes usually have short-focal ratios in the range of f/D = 0.3 to

0.45. Offset-fed dishes usually have longer focal lengths, with f/D = 0.45 to 0.80. If you attach two small mirrors to the outer front surface of a dish and then point the dish at the sun, you can easily find the focus point of the dish. This is where you want to place the feed source.

To invoke the flashlight analogy again, the feed source should evenly illuminate the entire dish, and none of the feed energy should fall outside the dish's reflecting surface. However, *no* feed system is perfect in illuminating a dish. These so-called "spillover losses" affect the gain by either under-illuminating or over-illuminating the dish. Typical dish efficiency is 50%. That's 3 dB of lost gain.

A great feed system for one dish can be a real lemon on another. For example, if you can get your hands on a surplus offset-fed satellite TV dish, you may find a helical radiator is the best feed source. Designs range anywhere from 2 to 6 turns. The two-turn helices are used for very short focal-length dishes in the f/D = 0.3 region, and the 6-turn helices are used with typically longer-focal-length ($f/D \sim 0.6$), offset-fed dishes. Generally speaking, helix feeds work poorly on the short-focal

length dishes, but really perform well on the longer-focal length, offset-fed dishes.

Parabolic antennas can be made from commercial or military surplus, including satellite TV dishes that you can "repurpose" in the finest Amateur Radio tradition. You will also find ham dealers selling so-called *barbecue grill* dishes that were originally designed for the Multichannel Multipoint Distribution Service, or "wireless cable TV"

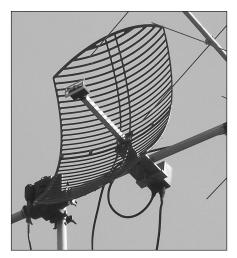

Figure 25 — The 2.4 GHz satellite downlink antenna at ARRL Headquarters station W1AW is a so-called "barbeque grill" dish antenna originally designed for the Multichannel Multipoint Distribution Service (MMDS). These inexpensive antennas can be assembled and installed in minutes.

(see **Figure 25**). MMDS antennas come with built-in feed sources at the focal points, so all you have to do is connect the feed line and go. These are among the most popular dish antennas for amateur satellite enthusiasts.

4.4 Antenna Mounting

One beneficial characteristic of satellite antennas is that they can be installed close to the ground as long as the antenna can "see" as much of the unobstructed sky as possible. Signals to and from the satellite will already be traversing hundreds or thousands of free space. So, adding a few more feet of elevation to your ground station antenna won't perceptibly improve the strength of those signals. What such an arrangement *will* do, however, is needlessly increase the length of coax (and corresponding line losses) between your transceiver and your antenna.

If your antennas already have an unobstructed view of the sky from the ground, you usually won't need a tower or roof installation unless trees or buildings surround the antennas and block their upward view. Or, to put it another way, your antenna support only needs to be high enough to make sure the back end of the antenna array is far enough off the ground to prevent people from walking into it while it's pointing straight up.

What's more, and as we have already discussed, satellite antennas (particularly those of the circularly polarized variety) along with their associated rotators (discussed below) tend to create a more complex antenna arrangement than that used for ordinary HF or

Figure 26 — A basic antenna rotator; the light-duty variety used to turn TV antennas. The wire exiting the bottom of the rotator housing is the multiconductor cable responsible for power and control.

VHF/UHF terrestrial operation. So, mounting them close to the ground makes performing any needed adjustments or repairs a whole lot simpler.

4.5 Antenna Rotators

If you plan to use directional antennas and don't wish to manipulate them by hand, you will need to install an *antenna rotator* (**Figure 26**). Making the correct decision as to how

much capacity the rotator must have is very important to ensure trouble-free operation.

Rotator manufacturers generally provide antenna surface area ratings to help you choose a suitable model. The maximum antenna area is linked to the rotator's torque capability. Some rotator manufacturers provide additional information to help you select the right size of rotator for the antennas you plan to use. Hy-Gain provides an Effective Moment value. Yaesu calls theirs a K-Factor. Both of these ratings are torque values in foot-pounds. You can compute the Effective Moment of your antenna by multiplying the antenna turning radius by its weight. So long as the effective moment rating of the rotator is greater than or equal to the antenna value, the rotator can be expected to provide a useful service life.

There are several rotator grades available to amateurs. The lightest-duty rotator is the type typically used to turn TV antennas. These rotators will handle smaller satellite antennas such as crossed Yagis. The problem with TV rotators is that they lack braking or holding capability. High winds can turn the rotator motor via the gear train in a reverse fashion, requiring realignment. Broken gears sometimes result.

The next grade up from the TV class of rotator usually includes a braking arrangement, whereby the antenna is held in place when power is not applied to the rotator. Generally speaking, the brake prevents antenna misalignment or gear damage on windy days. If adequate precautions are taken, this type of rotator is capable of holding and turn-

ing a stack of satellite antennas, including a parabolic dish which, by its nature, presents considerable wind loading. Keep in mind that as rotators increase in power, they become more expensive.

AZIMUTH/ELEVATION ROTATOR

Perhaps the ultimate in operating convenience is the *azimuth/elevation* (*az/el*) rotator. This rotator is capable of moving your antennas horizontally (azimuth) and vertically (elevation) at the same time. There are well-designed models available from Yaesu (**Figure 27**) and Alfa Radio (**Figure 28**). You can operate these rotators manually, or connect them to your computer for automated tracking. The downside is that az/el rotators tend to be expensive, typically around \$800 or more at this writing.

If your budget can stand the strain, az/el rotators are clearly worth the investment. On the other hand, if cost is an issue, consider using a standard rotator instead. While a traditional rotator can only move your antennas in the azimuth plane (horizontally), you can strike a compromise by installing the antennas at a permanent 45° tilt (**Figure 29**). This configuration will allow you to work the vast majority of satellites with reasonable success. You won't be able to follow the satellite when it is overhead or near the horizon, but you'll enjoy the lion's share of every pass.

Regardless of which type you choose, proper installation of the antenna rotator can provide many years of dependable service. Sloppy installation can cause problems such as a burned out motor, slippage, binding and even breakage of the rotator's internal gear and shaft castings or outer housing. Most ro-

Figure 28 — An az/el rotator made by Alfa Radio.

tators are capable of accepting mast sizes of different diameters, and suitable precautions must be taken to shim an undersized mast to ensure dead-center rotation.

If you decide to install your rotator on a tower, it is desirable to mount the rotator inside and below the top of the tower as far as possible. A long mast (10 feet or so) absorbs the torsion developed by the antenna during high winds, as well as during starting and stopping. Another benefit is mitigating the effect of any misalignment among the rotator, mast and the top of the tower.

A tube at the top of the tower (a *sleeve bearing*) through which the mast protrudes almost completely eliminates any lateral

forces on the rotator casing. All the rotator must do is support the downward weight of the antenna system and turn the array. Some installations use a *thrust bearing* mounted to the tower to support the weight of the antenna and mast.

Don't forget to provide a loop of coax to allow your antenna to rotate properly and allow water to drip off. Also, make sure you position the rotator loop so that it doesn't snag on anything.

COMPUTER CONTROL

As mentioned earlier, you can connect your rotator to your station computer and allow your satellite-tracking software to aim your

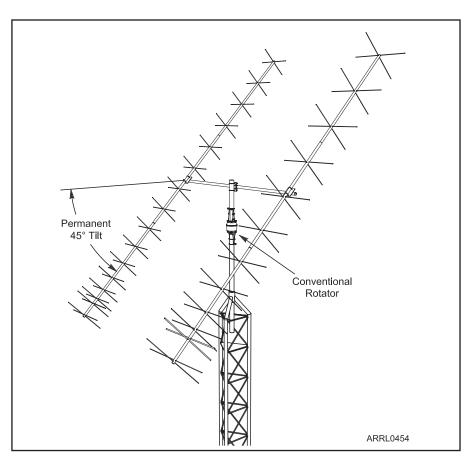

Figure 29 — The alternative to using an expensive azimuth/elevation antenna rotator is to simply install your antennas at a 45° tilt and use a conventional rotator to move them from side to side (azimuth only). This configuration will allow access during most satellite passes.

Figure 30 — The Yaesu GS-232 allows your computer and satellite tracking software to automatically control the movements of compatible azimuth/elevation antenna rotators.

antennas automatically (assuming your software supports rotator control). There used to be a number of commercial rotator/computer interface devices available for sale, but availability has dwindled over the years and those that remain tend to be expensive. An interface

such as the Yaesu GS-232 (**Figure 30**) costs about \$600 at the time of this writing. If you combine it with a Yaesu azimuth/elevation rotator, you will have invested almost \$1500 total. Less expensive alternatives are now found as kits or homebrew devices. A good

example is the G6LVB tracker interface at **www.g6lvb.com/Articles/LVBTracker**. If you're willing to build it yourself, you can probably put together an LVB unit for less than \$50. Do an Internet search and you'll no doubt uncover other homebrew interfaces.

5 Satellite Ground Station Equipment

5.1 Receive and Transmit Converters

Signals from satellites can be exquisitely weak, which means they need as much amplification as possible to be readable. Unfortunately, there are a number of factors that may conspire to weaken your radio's ability to render a decent received signal....

- You're using omnidirectional antennas. As discussed earlier, omni antennas lack much of the signal-capturing gain of directional antennas.
- The feed line between the antennas and the radio is long and/or contains "lossy" coax. Remember that even with the best coax,

the longer the feed line the more signal you'll lose, especially at higher frequencies.

• You're trying to communicate with a highorbiting satellite at apogee. When a signal travels up to 50,000 km to reach your station, even the gain of a directional antenna may not be sufficient.

PREAMPLIFIERS

The way to ensure that you have a useable received signal is to install a *receive preamplifier* (**Figure 31**) at the antenna. This is a highgain, low-noise amplifier with a frequency response tailored for one band only.

When shopping for a receive preampli-

fier, you want the most amount of gain for the least amount of noise. Every preamplifier adds some noise to the system, but you want the least additional noise possible. A well-designed UHF preamplifier, for example, may have gain on the order of 15 to 25 dB and a noise figure (NF) of 0.5 to 2 dB (less is better).

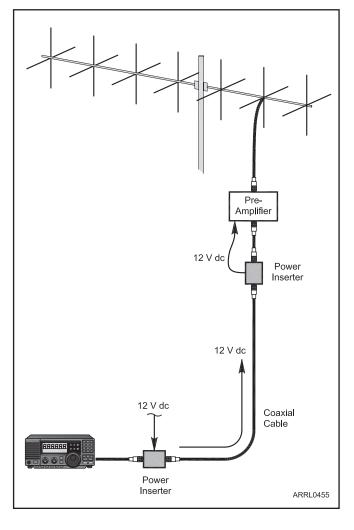

If your antennas are outdoors, look for preamplifiers that are "mast mountable." These preamplifiers are housed in weatherproof enclosures.

You will need to devise a means to supply dc power to the remote preamplifier. This can be as simple as routing a two-conductor power cable to the device. Alternatively, pre-

Figure 31 — This receive preamplifier by Advanced Receiver Research gives signals a substantial boost before they travel down the coaxial cable to your radio.

Figure 32 — A dc power inserter acts just as its name implies — it inserts a dc voltage to the coaxial cable at the station. The inserter is designed to block dc power from going "backward" to the radio. Instead, the power flows through the coax to the antenna where another inserter picks it off and supplies it to the device (a preamplifier, in this case). Both inserters pass RF with negligible loss.

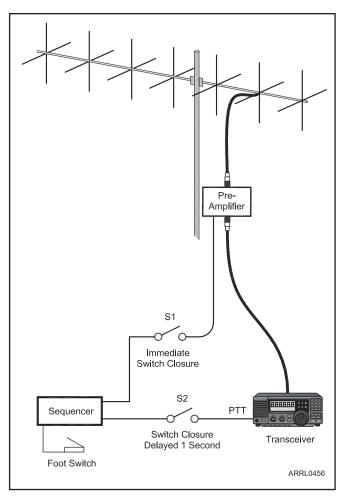

Figure 33 — In this simplified example, the sequencer is triggered when the operator presses the foot switch. It immediately closes switch S1, which activates a "bypass" relay in the receive preamplifier at the antenna, effectively removing it from the feed line circuit. One second later, the sequencer closes switch S2, which is connected to the transceiver PTT (Push To Talk) line, keying the radio and applying RF power.

amplifiers can be powered by dc sent up the feed line itself. Some transceivers have the ability to insert 12 V dc on the feed line for this purpose. If not, you can use a *dc power inserter* to inject power at the station and/or recover it nearer the antenna (see **Figure 32**). Some preamplifier designs include feed line power capability, so all you need is an inserter at the "station end."

If your preamplifier is going to be installed in a feed line that will also be carrying RF power from the radio, you'll need a model that includes an internal relay to temporarily switch it out of the circuit to avoid damage to the preamplifier when you're transmitting. Some preamplifiers include this relay and nothing more; it is up to you to provide the means to energize the relay before you transmit. This is accomplished through a device known as a *TR sequencer*. A sequencer works with your transceiver to automatically switch the preamplifier out of the feed line before

the radio can begin sending RF power (see **Figure 33**). A less complicated alternative is to purchase a preamplifier with *RF-sensed switching*. This design incorporates a sensor that detects the presence of RF from the radio and instantly switches the preamplifier out of harm's way. Note that RF-switched preamplifiers are rated according to the power they can safely handle. If you're transmitting 150 W, you'll need an RF-switched preamplifier rated for 150 W or more.

DOWNCONVERTERS

As the name implies, a *downconverter*, also known as a *receive converter*, converts one band of frequencies "down" to another. For example, a 2-to-10-meter downconverter would convert signals in a range from 144 to 146 MHz to 28 to 30 MHz.

In the days before HF/VHF/UHF transceivers, a downconverter was a popular means of receiving VHF and UHF signals by convert-

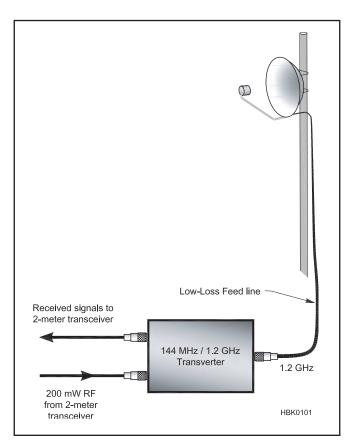

Figure 34 — In this example, the transverter is taking 1.2 GHz received signals and converting them to 2 m. When it's time to transmit, the transverter takes RF at 2 m and converts it to 1.2

ing them to 10 meters (usually) for reception on an HF receiver. Today downconverters are used more often as a way to receive microwave signals, for example converting a range of frequencies at 2.4 GHz to 2 meters. A microwave downconverter works best when installed right at the antenna so that the microwave energy is immediately converted to a lower frequency before excessive feed line loss can occur. See **Figure 34**.

Like receive preamplifiers, downconverters are rated by their gain and NF (the lower the NF, the better). When it comes to installing a downconverter, all the same receive preamplifier issues apply. If the downconverter is installed outdoors it must be in a weatherproof enclosure. You must also supply dc power and be able to switch the downconverter out of the line if you are sending RF power to the same antenna.

TRANSVERTERS

Transverters are related to downconverters in that they not only convert received signals, they convert transmitted signals as well. You can use a transverter to generate, say, a 1.2 GHz uplink signal when powered by RF energy from a 2 meter transceiver. The same transverter can convert 1.2 GHz downlink

Figure 35 — This downconverter by Downeast Microwave converts signals at 2.4 GHz to 2 m. With its weatherproof enclosure, it is designed to be installed at the antenna.

signals to 2 meters as well (Figure 35).

Transmit/receive switching in most transverters is accomplished through the use of an internal switch that is keyed through a sequencer. Some models provide automatic RF-sensed switching.

When working with transverters, one issue is supplying a safe level of RF power to the input. If your transceiver pumps out 50 W of power at 2 meters, for example, this is way too much RF for most transverters to handle. Unless the transverter has a built-in RF power attenuator, it is designed to deal with RF power levels on the order of *milliwatts* (typically 200 to 300 mW). If you are lucky enough to own a transceiver that features a transmit transverter port, you can obtain your milliwatt power levels there. If not, you'll need to add an attenuator at the transverter input to reduce the RF output of your radio to safe levels.

5.2 Transceivers

There are many amateur transceivers that cover the VHF and UHF bands. Some popular radios offer all the HF bands as well. Some of these transceivers offer satellite-specific features, while others are oriented toward terrestrial operation.

WORKING WITH FM REPEATER AND DIGITAL SATELLITES

Almost any dual-band (2 meter/70 cm) FM transceiver will be adequate for operating FM repeater satellites such as OSCAR 50, and for digital operating with the International Space Station or LEO orbiting birds as well (**Figure 36**). Getting started with a dual-band FM radio and a repeater satellite is a worthwhile option.

Most modern dual-band rigs offer a "high power" output setting around 50 W. That's more than enough power to put a solid signal into a satellite with a directional antenna. It is also sufficient for omnidirectional antennas, including mobile antennas. (Yes, you can

Figure 36 — The ICOM IC-2820 FM transceiver can receive and transmit on 2 m and 70 cm independently. With a dual-band FM rig like this, you can communicate through the FM repeater satellites, even while mobile.

Figure 37 — The Kenwood TM-D710 is a dual-band FM transceiver with a built-in packet radio Terminal Node Controller (TNC) for digital communication.

make contacts through FM repeater satellites while you drive!)

If you are considering digital operation, make sure to choose an FM transceiver that offers a data port. This will make it much easier to connect an external radio modem, such as a packet radio terminal node controller (TNC). There are even a few radios with TNCs already built in (Figure 37). Also, make sure the transceiver is rated to handle 1200 and 9600 baud data signals. Nearly all FM transceivers can work with 1200 baud, but 9600 baud is another matter. When in doubt, check the *QST* magazine Product Reviews. Look for the bit-error-rate (BER) test results.

You can use dual-band handheld transceivers to work the FM birds, but their RF output is so low (5 W or less) that you will definitely need to couple them to directional antennas to be heard consistently among the competing signals (**Figure 38**). What's more, at this writing, most of the newer handhelds will *not* allow so-called true (or "full") duplex operation. We will discuss what full-duplex means and why it is desirable for satellite work in a moment.

WORKING WITH LINEAR TRANSPONDER (SSB/CW) SATELLITES

FM signals tend to be wide and, by design, FM receivers are forgiving of frequency

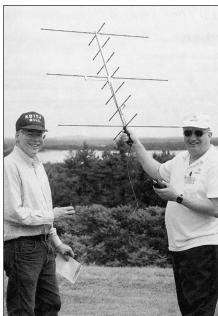

Figure 38 — The hand-held Arrow gain antenna is popular for FM repeater satellite operations. This is a dual band version for 2 meters and 70 cm. [AMSAT photo]

changes. That fortunate characteristic makes it easy to compensate for Doppler frequency shifting as an FM repeater satellite zips overhead.

SSB and CW signals are much narrower, however, and when you're working through a linear transponder satellite your signal is sharing the passband with several others. Not only do you need to adjust your receive (downlink) frequency almost continuously to keep the SSB voice or CW sounding "normal," you also have to stay on frequency to avoid drifting into someone else's conversation. The most effective way to do this is to listen to your own signal coming through the satellite in real time while you are transmitting on the uplink. This type of operation is known as *full duplex*.

You will find many multimode (SSB, CW, FM) transceivers that boast a feature labeled "cross-band split" or even "cross-band duplex." Be careful, though. What you require is a radio that can transmit and receive on different bands *simultaneously*. Few amateur transceivers can manage such a trick!

As this book went to press, there were only two all-mode amateur transceivers on the market that were capable of full duplex operation: The ICOM IC-9100 (Figure 39A) and the Kenwood TS-2000 (Figure 39B). However, if you shop the used equipment market you'll find excellent satellite radios such as the Yaesu FT-736 (Figure 40), the ICOM IC-820 and IC-910H, the Yaesu FT-726 and FT-847 along with the Kenwood TS-790. All of these transceivers have

Figure 39 — (A) The ICOM IC-9100 is an HF/ VHF/UHF transceiver with 23 cm available as an option. (B) The Kenwood

TS-2000 offers full HF coverage, plus VHF and UHF with full-duplex satellite capability.

Figure 40 — The Yaesu FT-736 is a legendary satellite transceiver. Although no longer manufactured, the '736 is still available on the used market.

full-duplex capability.

Another option that some hams have used successfully is to exploit computer control of their ordinary non-duplex multiband transceivers to compensate for Doppler shift. Some satellite-tracking programs can automatically change the frequency of your radio during a pass. They do this by mathematically calculating the frequency shift and tweaking your radio accordingly. This solution for frequency stability isn't as accurate as listening to your own downlink signal in full duplex, but it can work.

Another option is to use one transceiver for the uplink and a separate receiver or transceiver for the downlink. Some amateurs have even pressed old shortwave receivers into service along with VHF or UHF downconverters. They transmit with a 2 m or 70 cm SSB radio on the uplink while listening to their shortwave receiver/downconverter combo on the downlink.

If you are working a linear transponder satellite with an uplink at 1.2 GHz or higher, you'll likely have to take the transverter approach to getting on the air, although there are some transceivers that offer optional 1.2 GHz modules. Fortunately, satellite builders are well aware that most hams own 2 meter and 70 cm transceivers and they design new birds accordingly. Even transponders with microwave downlinks are usually configured with uplinks on 2 meter or 70 cm. So, if you purchase a VHF/UHF transceiver all you need to add is a downconverter to receive the microwave downlink.

Still another option for a downlink receiver is a software defined receiver (SDR) (see Figure 41). These receivers are powerful devices which can not only receive the desired frequency needed for the transmit frequency on the other transceiver; the software used with the SDR device could potentially display a waterfall showing the transponder. Many of the programs used with SDR devices can be

controlled by software like *SatPC32* or *Mac-Doppler*, in the same manner as the software would control a transceiver or receiver. A couple of popular SDR devices used by satellite operators include the FUNcube Dongle Pro+ and the software defined receivers made by SDRplay (RSP1, RSP2, RSP2pro).

5.3 VHF/UHF RF Power Amplifiers

If your chosen transceiver offers at least 50 W output on the uplink band, you won't need an RF power amplifier to bring your signal to a level that can be "heard" by a LEO satellite, especially if you are using directional antennas.

On the other hand, if you are using omni antennas, 100 or 150 W output may help considerably. And if your target is an HEO satellite orbiting at 50,000 km, 100 W or more, along with a directional antenna, is *mandatory*. If your transceiver lacks the necessary punch for the application, the solution is an external RF power amplifier.

How much power should you buy? In most cases, a 100 or 150 W amplifier is a good choice (**Figure 42**). As you shop for amplifiers, take care to note the input and output specifications. How much RF at the input is necessary to produce, say, 150 W at the output? Can your radio supply that much power?

Another consideration is your dc power supply. While a 25 A, 13.8 V dc supply is perfectly adequate to run a 100 W transceiver, if you also decide to add a 100 or 150 W amplifier to your satellite station, the current demands will increase considerably. A separate power supply may be required to provide an *additional* 20 A (or more) to safely power the amplifier when both the transceiver *and* the amplifier are transmitting at the same time.

Figure 41 — Some examples of software defined receivers used for satellite operating. Upper left: SDRplay RSP1. Upper right: SDRplay RSP2. Bottom center: FUNcube Dongle Pro+.

5.4 Typical Station Designs

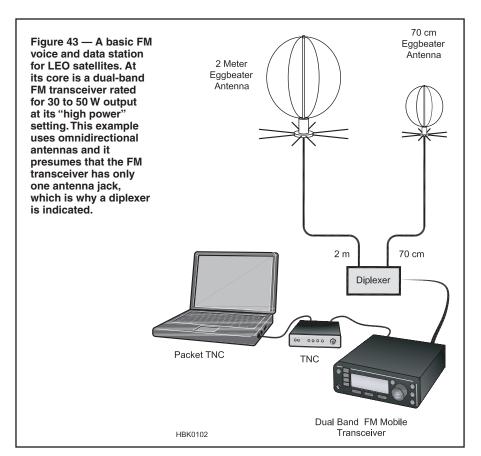

Since there are so many station equipment options available, it may be helpful to outline a few typical station configurations.

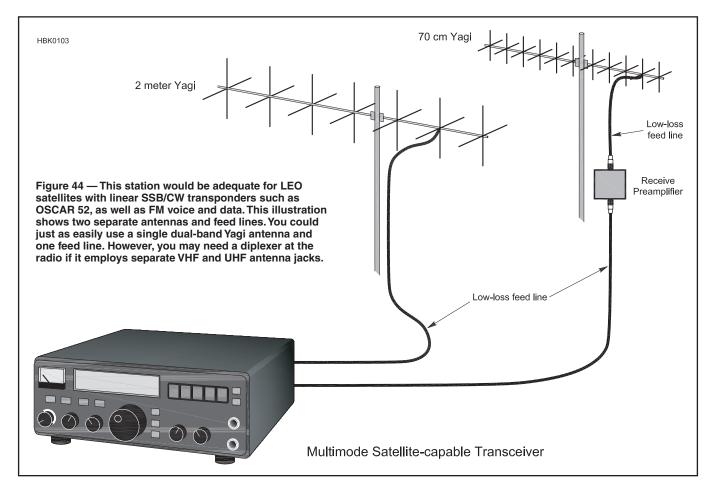

Figure 43 illustrates a basic FM voice and data station for LEO satellites. At its core is a dual-band FM transceiver rated for 30 to 50 W output. The example uses omnidirectional antennas and it presumes that the FM transceiver has only one antenna jack, which is why a diplexer is indicated. Otherwise, you could run two separate coaxial feed lines back to the radio.

The performance of this station can be substantially enhanced by adding directional antennas or a dual-band Yagi but, of course, that will require an antenna rotator (human or mechanical!).

In **Figure 44** we've stepped up to a multiband, multimode transceiver with full duplex capability and directional antennas. This station would be excellent for LEO satellites with linear SSB/CW transponders such as OSCAR 29, as well as other modes like data and FM voice. By adding an RF power amplifier (assuming the output of the radio is less than 100 W), this station would be capable of working distant high-orbiting satellites as well.

Note that this illustration shows two separate antennas and feed lines. You could just

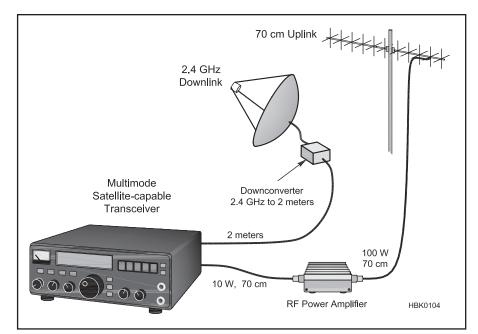

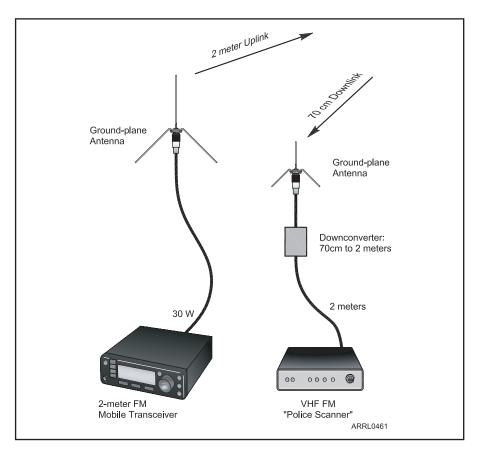

Figure 45 — This example illustrates a station designed to work a distant Phase III or IV satellite with a microwave downlink. It assumes that the uplink is at 70 cm and the downlink is at 2.4 GHz. Note the use of the downconverter to step the 2.4 GHz signal at the antenna down to 2 meters before it is fed to the radio.

as easily use a single dual-band Yagi antenna and one feed line. However, you may need a diplexer at the radio if it employs separate VHF and UHF antenna jacks.

Figure 45 addresses at least one method to work satellites with microwave downlinks. It assumes that the uplink is at 70 cm and the downlink is at 2.4 GHz. It also assumes that the satellite in question is a high-orbiting spacecraft (note the RF power amp on the uplink).

Note also the use of the downconverter to step the 2.4 GHz signal at the antenna to 2 meters before it is fed to the radio. You can actually use this same approach for any combination of bands and radios. For instance, let's say that you want to work the low-orbiting FM birds, but you have only a 2 meter FM transceiver for the uplink and a separate VHF FM police scanner receiver for the downlink. You could use a downconverter for the 70 cm downlink, stepping the signal down to 2 meters for reception with the scanner (**Figure 46**).

Figure 46 — Let's say that you want to work the low-orbiting FM birds, but you only have a 2 meter FM transceiver for the uplink and only a VHF FM "police scanner" receiver for the 70 cm downlink. You could use a downconverter for the 70 cm downlink, stepping the signal down to 2 meters for reception with the scanner.

6 Satellite Antenna Projects

6.1 An EZ-Lindenblad Antenna for 2 Meters

This easy-to-build antenna project by Anthony Monteiro, AA2TX, works well for satellite or terrestrial communication. It is circularly polarized yet has an omnidirectional radiation pattern (no rotator needed to track satellites). With most of its gain at low elevation angles, it is ideal for accessing LEO amateur satellites. It is good for portable operation or general-purpose use at home stations because its circular polarization is compatible with the linearly polarized antennas used for FM/repeater and SSB or CW operation.

This type of antenna was devised by Nils Lindenblad of the Radio Corporation of America (RCA) around 1940. His idea was to employ four dipoles spaced equally around a $\lambda/3$ diameter circle with each dipole canted 30° from the horizontal. The dipoles are all fed in phase and are fed equal power. The spacing and tilt angles of the dipoles create the desired antenna pattern when the signals are all combined. After WWII, George Brown and Oakley Woodward, also of RCA, were tasked with finding ways to reduce fading on ground-to-air radio links at airports and built on Lindenblad's design.

While the Brown and Woodward design is clever and worked well, it would be difficult for the home builder to duplicate because of the need for the four-way, in-phase, power splitting function. Since amateurs generally want to use 50 Ω coaxial cable feed line, we have to somehow provide an impedance match from the 50 Ω unbalanced coax to the four 75 Ω balanced dipole loads. Previous designs have used combinations of folded dipoles, open-wire lines, twin-lead feeds, balun transformers and special impedance matching cables to try to get a good match to 50 Ω . These in turn increase the complexity and difficulty of the construction.

THE EZ-LINDENBLAD

The key concept of the EZ-Lindenblad is to eliminate anything electrically or mechanically difficult. This leads to the idea of just feeding the four dipoles with coax cable and soldering the cables to a connector with no impedance matching devices at all. This would certainly be *easy* but we also want the antenna to work! Without the extra impedance matching devices, how is it possible to get a good match to $50~\Omega$?

If we could get each of the four coax feed cables to look like $200\,\Omega$ at the connector, then the four in parallel would provide a perfect match to $50\,\Omega.$ We could do this if we used $1/4\,\lambda$ sections of $122\,\Omega$ coax to convert each $75\,\Omega$ dipole load to $200\,\Omega.$ Unfortunately, there is no such coax that is readily available.

But we can accomplish the same thing with ordinary $75\,\Omega$, RG-59 coax if we run the cable with an intentional impedance mismatch. By forcing the standing wave ratio (SWR) on the cable to be equal to 200/75, or about 2.7:1, we can make each cable look exactly like $200\,\Omega$ at the connector as long as we make them the right length. It is easy to make the SWR equal 2.7:1 by just making the dipoles a little too short for resonance. An *EZNEC* (www.eznec. com) antenna model can be used to determine the exact dipole dimensions.

The conversion from the balanced dipole load to unbalanced coax cable can be accomplished by threading each cable through a ferrite sleeve making a choke balun. The only remaining issue is the required length of the feed cables. With a Smith Chart or software, we can easily determine the required length of 75 Ω coax to provide a 200 Ω load. An EZNEC antenna model was used to simulate cutting the dipole lengths until the SWR on the line reached 2.7:1. The model showed that the dipole load impedance would then be $49-j55 \Omega$. Plotting that value and the desired 200 Ω impedance at the connector on the chart and drawing a constant 2.7:1 SWR curve between the two impedance points, the length of the line needed is 0.374λ . (For more information about this process, see www.arrl.org/ **smith-chart** or the *TLW* software provided with *The ARRL Antenna Book.*)

The EZ-Lindenblad was designed for a center frequency of 145.9 MHz to optimize its performance in the satellite sub band. At 145.9 MHz, a wavelength is about 81 inches and since the coax used has a velocity factor

of 0.78, we need to make the feed cables 81 \times 0.374 \times 0.78 = 23.6 inches long.

It's imperative that stranded RG-59A foam PE dielectric coax be used. The solid-dielectric cable has a velocity factor of 66% and will not work. The author used part #RG59A-100 from www.l-com.com. This is a 100 ft roll; for one antenna you could buy L-Com part #CCF59-12, a 12 ft jumper, and cut it to the required length. Belden 9259 is another suitable cable.

CONSTRUCTION

This antenna was designed to be rugged and reliable yet easy to build using only hand tools with all of the parts readily available as well (see **Table 5**). Although not critical, the construction will be easier if the specified 17 gauge aluminum tubing is used since the inner wall of the tubes will be just slightly smaller than the outer wall of the PVC insert Ts used to connect them. If heavier gauge tubing is used, it will be necessary to file down the PVC insert Ts to make them fit inside the aluminum tubes.

Start by making a mounting bracket to mount the N-connector and the cross booms. Cut a 5/8 inch hole in one side of the short piece of angle stock and rivet or screw it to the bottom of the long piece of angle stock. The completed bracket with the connector and cables attached can be seen in **Figure 47**.

Next, cut the aluminum tubing to make the cross booms and dipole rods as shown in **Figure 48**. Drill holes for the sheet metal screws at each end of the cross booms but do not insert the screws yet. Attach the cross

Table 5

Required Materials

Quantity one, unless noted.

- Aluminum tubing, 17 gauge, 6 ft length of % in OD, quantity 3. Available from Texas Towers, www.texastowers.com.
- Aluminum angle stock, 8 in length of $2 \times 2 \times \frac{1}{16}$ in
- Aluminum angle stock, 2 in length of 2 × 2 × 1/16 in for mounting connector.
- Screws, $\#8 \times \frac{1}{2}$ in aluminum sheet metal, quantity 12.
- Screws, #8 \times ½ in aluminum sheet metal or $\frac{3}{16}$ in aluminum rivets, quantity 12.
- PVC insert T-connector, ½ x ½ x ½ in grey for irrigation polyethylene tubing. LASCO
 Fittings, Inc. Part# 1401-005 or equivalent. Available from most plumbing supply and major
 hardware stores, quantity 4.
- Plastic end caps (optional), black ¾ in, quantity 8.
- N-connector for RG-8 cable, single-hole, chassis-mount, female.
- Cable ferrite, Fair-Rite part #2643540002, quantity 4 (Mouser Electronics #623-2643540002).
- RG-59A polyethylene foam coax with stranded center conductor (Belden 9259 or equiv; must be foam PE dielectric with 78% velocity factor, not solid dielectric), 10 ft length.
- Copper braid, 4 in long piece.
- Ring terminal, uninsulated 22-18 gauge for 8-10 stud, quantity 4.
- Ring terminal, uninsulated 12-10 gauge for 8-10 stud, quantity 4.
- Heat shrink tubing for ¼ in cable, wire ties, electrical tape, as needed.
- Ox-Gard OX-100 grease for aluminum electrical connections.

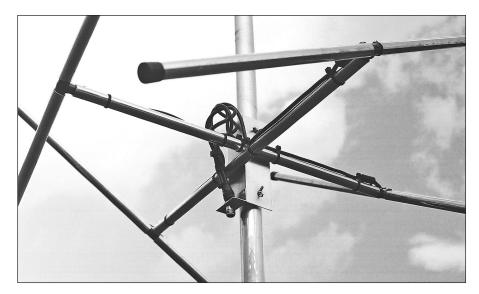

Figure 47 — View of cross booms mounted to mast.

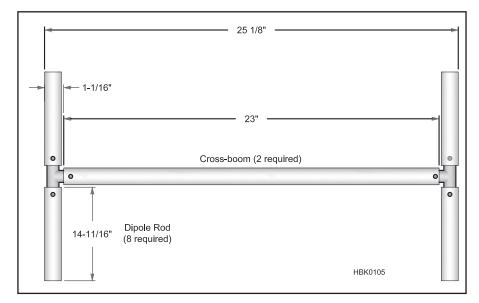

Figure 48 — Dimensions of the dipoles and cross booms. The antenna requires two cross booms, with a dipole at each end of each cross boom (four dipoles total).

booms to the long section of angle stock with rivets or screws. One cross boom will mount just above the other as can be seen in Figure 47. The cross booms should be perpendicular to the mounting bracket so that they will be horizontal when the antenna is mounted to its mast. Make sure that the centers of the cross booms are aligned with each other so that the ends of the cross booms are all 11.5 inches from the center cross.

Make the dipoles by inserting a PVC insert T into two dipole rods. It should be possible to gently tap in the rods with a hammer but it may be necessary to file down the insert T a little if the fit is too tight. Applying a little PVC cement to the insert T will soften the plastic and make it easier to insert into the aluminum tubing if the fit is too tight. The overall dipole length dimension is critical so take care to get this correct as shown in **Figure 49**.

Drill holes for screws in each dipole rod but do not insert the screws yet. The screws will be used to make the electrical connections to the dipoles at the center. The screw holes should be about 3/8 inches from the end of the tubing.

The dipole assemblies are attached by gently tapping the PVC insert-T into the end of each cross-boom with a hammer. The dimensions are shown in Figure 48.

Next, temporarily attach the mounting bracket to a support so that each of the cross booms is perfectly horizontal. Measure this with a protractor. Now, using the protractor, rotate the dipole assemblies to a 30° angle with the right-hand side of the nearest dipole tilting up when you are looking toward the center of the antenna. Drill a small hole through the existing cross-boom holes into the PVC insert-Ts and then use the sheet metal screws to fasten the dipole assemblies into place. For a nice finishing touch, the dipole ends can be fitted with 3/4 inch black plastic end caps.

Next, make the four feed cables by cutting and stripping the RG-59A as shown in **Figure 50**. On the dipole connection side, unwrap

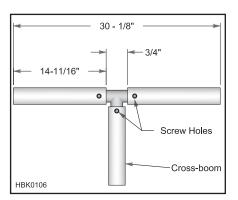

Figure 49 — Dipole assembly dimensions.

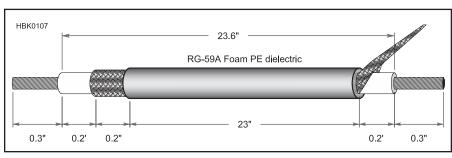

Figure 50 — Feed cables stripping dimensions.

Figure 51 — Close-up of dipole electrical connections.

the braid and form a wire lead. Apply the smaller ring terminal to the center conductor and use the larger ring terminal for the braid. At the other end of the cable, do not unwrap the braid but strip off the outer insulation. Slip a 1 inch piece of shrink wrap over the coax and apply to the dipole side. Next slip a cable ferrite over the cable and push all the way to the dipole end as far as it will go (ie, up to the heat-shrink tubing.) The fit will be snug and you may need to put a little grease on the cable jacket to get it started.

Prepare each dipole for its feed cable by first cleaning the area around the screw holes with steel wool and then applying Oxy-Gard or other corrosion resistant electrical grease. The coax center conductor goes to the up side of the dipole and the braid goes to the down side. To make a connection, put a screw through the ring terminal and gently screw into the dipole tubing. Do not overtighten the screws or you will strip the tubing. **Figure 51** shows the completed connections.

Apply Oxy-Gard around the hole for the N connector. Take the 4 inch piece of braid and put the end of it through the hole for the N connector. This provides the ground connection. Secure the N connector in the mounting hole to clamp the braid. Use a wire tie or tape to hold the four feed cables together at the connector ends. Make sure to align the cables so that all the ground braids are together and the center conductors all extend out the same amount. Do not twist the center conductors together. Carefully push the four cable center conductors into the center terminal of the N connector and solder them in place. Wrap the exposed center conductors of the cables and the connector with electrical tape.

Take the piece of braid that is clamped to the N connector and wrap it around the four exposed ground braids of the coax cables. Solder them all together. This will take a fair amount of heat but be careful not to melt the insulation. After this cools, apply electrical tape over all the exposed braid and fix with

Figure 52 — The EZ-Lindenblad as a portable or Field Day antenna. A 70 cm antenna is on the top.

wire ties. Secure the cables to the cross booms with wire ties.

The mounting bracket provides a way to attach the antenna to a mast using whatever clamping mechanism is convenient (eg, Ubolts). The author's antenna was intended for portable operation and the bracket was drilled to accept two #8 machine screws. These screws pass through a portable mast and the antenna is secured with wing nuts for easy setup. The completed portable antenna is shown in **Figure 52**. The little antenna at the top is for 70 cm.

PERFORMANCE

The antenna impedance match to $50\,\Omega$ was tested using an MFJ-259B SWR meter, which was checked against an external frequency counter and precision $50\,\Omega$ load. The antenna provides an excellent match over the entire 2 meter band. This antenna was designed to safely handle any of the currently available VHF transceivers and tested by applying a 200 W signal key down for 9 minutes, then checking the ferrites and cables for temperature rise.

The antenna radiation pattern predicted by the *EZNEC* model is shown in **Figure 53**. This is the elevation plot with the antenna

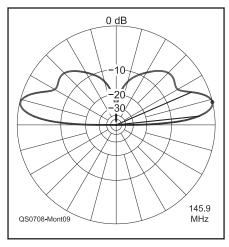

Figure 53 — *EZNEC* elevation radiation pattern of Lindenblad antenna.

mounted at 6 ft above ground although it can be mounted higher if desired for better coverage to the horizon. As shown in the plot, the pattern favors the lower elevation angles. The –3 dB points are at 5° and 25° with the maximum gain of 4.8 dBic (dB with respect to an isotropic circularly polarized antenna) at around 13°. Most of the satellite pass elevations will be in this range and it is also the elevation at which the satellite provides the best chance for DX contacts. The antenna radiation is right-hand circularly polarized, which will work with virtually any LEO satellite that uses the 2 meter band.

The EZ-Lindenblad antenna has been used for SSB, FM and packet operation on a number of amateur satellites. A portable setup performed well on Field Day, an excellent test of any antenna as it is probably the busiest weekend of the year on the satellites.

6.2 The W3KH Quadrifilar

If your existing VHF omnidirectional antenna coverage is "just okay," this twisted antenna project by Eugene F. Ruperto, W3KH, is probably just what you need! The everchanging position of LEO satellites presents a problem for the Earth station equipped with a fixed receiving antenna: signal fading caused by the orientation of the propagated wavefront. This antenna provides a solution to the problem and can be used with weather satellites, or any of the polar-orbiting amateur satellites

Several magazines have published articles on the construction of the quadrifilar helix antenna (QHA) originally developed by Dr Kilgus.¹ A particularly good reference is

¹C.C.Kilgus, "Resonant Quadrafilar Helix;" IEEE Transactions on Antennas and Propagation, Vol AP-17, May 1969, pp 349-351. Reflections by Walt Maxwell, W2DU, who had considerable experience evaluating and testing this antenna while employed as an engineer for RCA.²

Part of the problem of replicating the antenna lies in its geometry. The QHA is difficult to describe and photograph. Some of the artist's renditions leave more questions than answers, and some connections between elements as shown conflicted with previously published data. However, those who have successfully constructed the antenna say it is *the* single-antenna answer to satellite reception for the low-Earth-orbiting satellites.

DESIGN CONSIDERATIONS

Experts imply that sophisticated equipment is necessary to adjust and test the antenna, but the author found it possible to construct successful QHAs by following a cookbook approach using scaled figures from a proven design. The data used as the design basis for the antenna described here were published in an article describing the design of a pair of circularly polarized S-band communicationsatellite antennas for the Air Force and designed to be spacecraft mounted.³ Using this antenna as a model, the author constructed QHAs for the weather-satellite frequencies and the polar-orbiting 2 meter and 70 cm amateur satellites with excellent results and without the need for adjustments and tuning. By following some prescribed universal calculations, a reproducible and satisfactory antenna can be built using simple tools.

UHF and microwave antennas require a high degree of constructional precision because of the antenna's small size. For instance, the antenna used for the Air Force at 2.2 GHz has a diameter of 0.92 inch and a length of 1.39 inches! On the other hand, a QHA for 137.5 MHz is 22.4 inches long and almost 15 inches in diameter; for 2 meters, the antenna is not much smaller. Antennas of this size are not difficult to duplicate.

ELECTRICAL CHARACTERISTICS

A half-turn 1/2 λ QHA has a theoretical gain of 5 dBi and a 3-dB beamwidth of about 115°, with a characteristic impedance of 40 Ω . The antenna consists basically of a four-element, half-turn helical antenna, with each pair of elements described as a *bifilar*; both of which are fed in phase quadrature. Several feed methods can be employed, all of which appear complicated except the infinite-balun design, which uses a length of coax as one of the four elements.

 M.W. Maxwell, W2DU, Reflections (Newington: ARRL, 1990). [This book is out of print.]
 R. Brickner Jr and H. Rickert, "An S-Band Resonant Quadrifilar Antenna for Satellite Communication," RCA Corp, AstroElectronics Div.

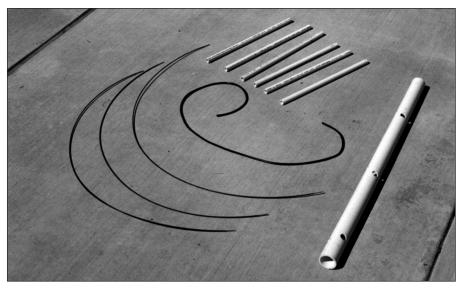

Figure 54 — The quadrifilar helix antenna (QHA) pieces, ready for assembly.

To produce the necessary 90° phase difference between the bifilar elements, either of two methods can be used. One is to use the same size bifilars, which essentially consist of two twisted loops with their vertical axes centered and aligned, and the loops rotated so that they're 90° to each other (like an eggbeater), and using a quadrature hybrid feed. Such an antenna requires *two* feed lines, one for each of the filar pairs.

The second and more practical method is the self-phasing system, which uses different-size loops: a larger loop designed to resonate below the design frequency (providing an inductive reactance component) and a smaller loop to resonate higher than the design frequency (introducing a capacitive-reactance component), causing the current to lead in the smaller loop and lag in the larger loop. The element lengths are $0.560\,\lambda$ for the larger loop, and $0.508\,\lambda$ for the smaller loop. According to the range tests performed by Maxwell, to achieve optimum circular polarization, the wire used in the construction of the bifilar elements should be $0.0088\,\lambda$ in diameter.

Maxwell indicates that in the quadrifilar mode, the fields from the individual bifilar helices combine in optimum phase to obtain unidirectional end-fire gain. The currents in the two bifilars must be in quadrature phase. This 90° relationship is obtained by making their respective terminal impedances R + jXand R - iX where X = R, so that the currents in the respective helices are -45° and $+45^{\circ}$. The critical parameter in this relationship is the terminal reactance, X, where the distributed inductance of the helical element is the primary determining factor. This assures the $\pm 45^{\circ}$ current relationship necessary to obtain true circular polarization in the combined fields and to obtain maximum forward radiation and

Figure 55 — The antenna with two of the four legs (filars) of one loop attached.

minimum back lobe. Failure to achieve the optimum element diameter of $0.0088 \, \lambda$ results in a form of elliptical, rather than true circular polarization, and the performance may be *a few tenths of a decibel* below optimum, according to Maxwell's calculations. Using #10 wire translates roughly to an element diameter of $0.0012 \, \lambda$ at $137.5 \, \text{MHz}$ — not ideal, but good enough.

To get a grasp of the QHA's topography, visualize the antenna as consisting of two concentric cylinders over which the helices are wound (see **Figure 54** through **Figure 58**). In two-dimensional space, the cylinders

Figure 56 — This view shows the QHA with all four legs in place. The ends of the PVC cross arms that hold the coaxial leg are notched; the wire elements pass through holes drilled in the ends of their supporting cross arms.

can be represented by two nested rectangles depicting the height and width of the cylinders. The width of the larger cylinder (or rectangle) can be represented by 0.173 λ and the width of the smaller cylinder represented by 0.156 λ . The length of the larger cylinder or rectangle can be represented by 0.260 λ , and the length of the smaller rectangle or cylinder can be represented by 0.238 λ . Using these figures, you should be able to scale the QHA to virtually any frequency. **Table 6** shows some representative antenna sizes for various frequencies, along with the universal parameters needed to arrive at these figures.

PHYSICAL CONSTRUCTION

Figure 59 shows the construction details. A 25-inch-long piece of schedule 40, 2-inch-diameter PVC pipe is used for the vertical member. The cross arms that support the helices are six pieces of ½-inch-diameter PVC tubing: three the width of the large rectangle or cylinder, and three the width of the smaller

Figure 57 — Another view of the QHA.

Figure 58 — An end-on view of the top of the QHA prior to soldering the loops and installing the PVC cap.

cylinder. Two cross arms are needed for the top and bottom of each cylinder. The cross arms are oriented perpendicularly to the vertical member and parallel to each other. A third cross arm is placed midway between the two at a 90° angle. This process is repeated for the smaller cylindrical dimensions using the three smaller cross arms with the top and bottom pieces oriented 90° to the large pieces.

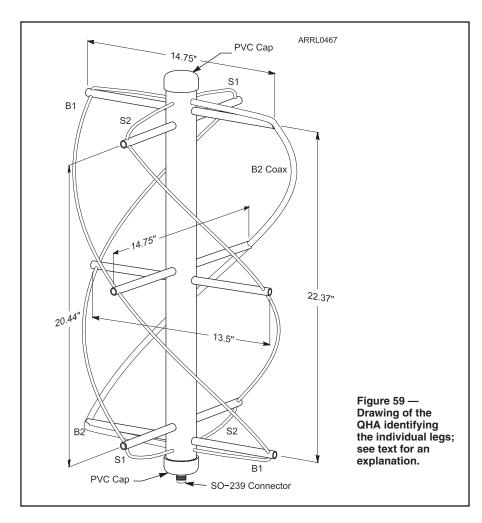

Using 5/8 inch-diameter holes in the 2-inch pipe ensures a reasonably snug fit for the ½-inch-diameter cross pieces. Each cross arm

is drilled (or notched) at its ends to accept the lengths of wire and coax used for the elements. Then the cross arms are centered and cemented in place with PVC cement. For the 137 and 146 MHz antennas, use #10 AWG copper clad antenna wire for three of the helices and a length of RG-8 for the balun, which is also the fourth helix. (Do not consider the velocity factor of the coax leg for length calculation.) For the UHF antennas, use #10 AWG soft-drawn copper wire and RG-58 coax. Copper clad wire is difficult to work with, but holds its shape well. Smaller antennas can be built without the cross arms because the wire is sufficiently self-supporting.

To minimize confusion regarding the connections and to indicate the individual legs of the helices, label each loop or cylinder as B (for big) and S (for small); T and B indicate top and bottom. Each loop can be further split using leg designators as B1T and B1B, B2T and B2B, S1T and S1B and S2T and S2B, with B2 being the length of coax and the other three legs as wires. For righthand circular polarization (RHCP) wind the helices *counterclockwise* as viewed from the top. This is contrary to conventional axial mode

Table 6
Quadrifilar Helix Antenna Dimensions

			Small Loop			Big Loop	
Freq	Wavelength	Leg Size	Diameter	Length	Leg Size	Diameter	Length
(MHz)	(λ) (inches)	(0.508λ)	(0.156λ)	(0.238λ)	(0.560 λ)	(0.173λ)	(0.261λ)
137.5	85.9	43.64	13.4	20.44	48.10	14.86	22.33
146	80.9	41.09	12.6	19.25	45.30	14.0	21.03

helix construction. (For LHCP, the turns rotate *clockwise* as viewed from the top.) See **Figure 60** for the proper connections for the top view. When the antenna is completed, the view shows that there are two connections made to the center conductor of the coax (B2) top. These are B1T and S1T, for a total of three wires on one connection. S2T connects to B2T braid. The bottom of the antenna has S1B and S2B soldered together to complete the smaller loop. B1B and the braid of B2B are soldered together. Attach an SO-239 connector to the bottom by soldering the center

conductor of B2B to the center of the connector and the braid of B2B to the connector's shell. The bottom now has two connections to the braid: one to leg B1B, the other to the shell of the connector. There's only one connection to the center conductor of B2B that goes to the SO-239 center pin.

Total price for all new materials-including the price of a suitable connector-should be in the neighborhood of \$10 or less.

RESULTS

With a 70-foot section of RG-9 between

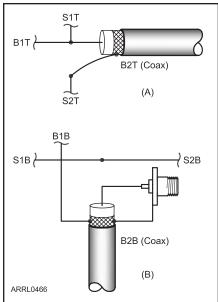

Figure 60 — At A, element connections at the top of the antenna. B shows the connections at the bottom of the antenna. The identifiers are those shown in Figure 59 and explained in the text.

the receiver and antenna, which is mounted about 12 feet above ground, and a preamp in the shack the author receives fade-free passes from the weather satellites. Although the design indicates a 3-dB beamwidth of 140°, an overhead pass provides useful data down to 10° above the horizon. The 70 cm antenna works fine for PACSATs, although Doppler effect makes manual tracking difficult. The weather-satellite antenna prototype worked better than expected and a number of copies built by others required no significant changes.

Thanks to Chris Van Lint, and Tom Loebl, WA1VTA, for supplying technical data to complete this project, and to Walt Maxwell, W2DU, for his review and technical evaluation and for sharing his technical expertise with the amateur satellite community.

8 Earth-Moon-Earth (EME) Communication

EME communication, also known as moonbounce, has become a popular form of amateur space communication. The EME concept is simple: the Moon is used as a passive reflector for two-way communication between two locations on Earth (see Figure 61). With a total path length of about half a million miles, EME may be considered the ultimate DX. Very large path losses suggest big antennas, high power and the best low noise receivers; however, the adoption of modern coding and modulation techniques can significantly reduce these requirements from their 20thcentury levels. Even so, communication over the EME path presents unusual station design challenges and offers special satisfaction to those who can meet them.

8.1 Background

EME is a natural and passive propagation phenomenon, and EME QSOs count toward WAC, WAS, DXCC, WAZ, and VUCC awards. EME opens up the bands at VHF and above to a new frontier of worldwide DX.

Professional demonstrations of EME capability were accomplished shortly after WW II. Amateurs were not far behind, with successful reception of EME echoes in 1953 and pioneering two-way contacts made on the 1296, 144, and 432 MHz bands in the 1960s. Increased EME activity and advances to other bands came in the 1970s, aided by the availability of reliable low-noise semiconductor devices and significant improvements in the design of Yagi arrays and feed antennas for parabolic dishes. These trends accelerated further in the 1980s with the advent of low-noise GaAsFET and HEMT preamplifiers and computer-aided

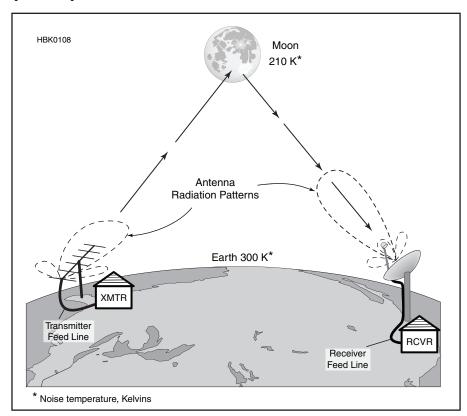

Figure 61 — Schematic representation of major system components for a (one-way) EME path. This illustration also shows some of the factors contributing to system noise temperature, which is discussed later in the chapter.

antenna designs, and again after 2000 with the introduction of digital techniques. See the sidebar, "Amateur EME Milestones."

EME QSOs have been made on all amateur bands from 28 MHz to 47 GHz. Many operators have made WAC, WAS and even DXCC on one or more of the VHF and UHF bands. EME is now within the grasp of most serious VHF, UHF, and microwave operators.

9 EME Propagation

9.1 Path Loss

Path loss in free space is caused by nothing more than the spherical expansion of a radio wave as it propagates away from an antenna. An EME signal is attenuated as $1/d^2$ (inverse distance squared) over the quarter-million mile path to the Moon, and again as $1/d^2$ on the return trip, for a net $1/d^4$ path loss. Radio waves incident on the surface of the Moon are often said to be "reflected," although in fact they are partly absorbed and partly scattered by the irregular lunar surface. A full expression giving the EME path loss as a ratio of received power to transmitted power, assuming isotropic antennas at each end of the path, is

$$\ell = \frac{\eta r^2 \lambda^2}{64 \, \pi^2 d^4} \tag{1}$$

where

r is the radius of the Moon

 λ is the wavelength

d is the distance to the Moon

η is the lunar reflection coefficient.

In this section we use the convention of lowercase letters to denote dimensionless ratios, and the corresponding upper-case letters to give equivalent values in dB. Thus, the EME path loss in dB is given for isotropic antennas by the expression

L=10 log
$$\ell = 10 log \left(\frac{\eta r^2 \lambda^2}{64 \pi^2 d^4} \right)$$
 (2)

Inserting values $r = 1.738 \times 10^6$ m, $d = 3.844 \times 10^8$ m and $\eta = 0.065$ gives the average path losses quoted in **Table 7** for the principal amateur EME bands. The need to overcome these very large attenuations is of course the main reason why EME is so challenging. The Moon's orbit is an ellipse, and its distance d varies by $\pm 6.8\%$ over each month. Because

of the inverse-fourth-power law in Equations (1) and (2), this change results in path-loss variations of ± 1.1 dB at the extremes of lunar distance, independent of frequency. The reflection of radio waves is of course not affected by the optical phases of the Moon.

The dependence of path loss on l^2 suggests that EME should be nearly 20 dB more difficult at 1296 MHz than at 144 MHz. This conclusion is misleading, however, because of the assumption of isotropic antennas. If one uses transmitting and receiving antennas of gain g_t and g_p expressed as ratios, the expected power p_r received as a lunar echo may be written as the product

$$p_r = p_t g_t g_r \ell \tag{3}$$

where p_t is the transmitted power. The standard expression for an antenna's power gain is

$$g = 4\pi A/l^2$$

Table 7 Two-Way EME Path Loss with Isotropic Antennas

Frequency	Average Path Loss
(MHz)	(dB)
50	-242.9
144	<i>–</i> 252.1
222	-255.8
432	-261.6
902	-268.0
1296	<i>–</i> 271.2
2304	-276.2
3456	-279.7
5760	-284.1
10368	-289.2
24048	-293.5

where A is the effective aperture or collecting area. Gain in dBi (dB over an isotropic antenna) may therefore be written as

 $G = 10\log (4\pi A/l^2)$

With P_r and P_t expressed in dB relative to some reference power, for example 1 W, we have

$$P_r = P_t + G_t + L + G_r \tag{4}$$

Thus, assuming a fixed size of antenna, such as a parabolic dish or Yagi array of effective frontal area A, the frequency dependence is reversed: for a given transmitted power, lunar echoes would be 20 dB stronger for every decade increase in frequency, rather than 20 dB weaker. Most practical situations fall somewhere between these two extremes of frequency dependence.

For reasons explained in detail below, amateur EME communication is feasible with roughly comparable degrees of difficulty over nearly two decades of frequency, from 144 MHz to 10 GHz. Not surprisingly, some very different techniques must be mastered in order to do successful EME at the lower and upper extremes of this wide frequency range — so the final choice of band(s) for EME is often determined by the interests, skills and resources of an individual operator.

9.2 Echo Delay and Time Spread

Radio waves propagate at speed c, the speed of light, very nearly equal to 3×10^8 m/s. Propagation time to the Moon and back is therefore 2d/c or about 2.4 s at perigee, 2.7 s at apogee and 2.56 s on average. The Moon is nearly spherical, and its radius corresponds to r/c = 5.8 ms of wave travel time. The trailing parts of an echo, reflected from irregular surface features near the edge of the lunar disk, are delayed from the leading edge by as much as twice this value. In practice, most of the Moon's surface appears relatively smooth at the radio wavelengths used for amateur EME. Lunar reflections are therefore quasispecular, like those from a shiny ball bearing, and the power useful for communication is mostly reflected from a small region near the center of the disk. At VHF and UHF frequencies, the effective time spread of an echo amounts to no more than 0.1 ms.

Reflection from a smooth surface preserves linear polarization and reverses the sense of circular polarization. At shorter wavelengths the lunar surface appears increasingly rough, so reflections at 10 GHz and above contain a significant diffuse component as well as a

quasi-specular component. The diffuse component is depolarized, and significant portions of it arise from regions farther out toward the lunar rim. The median time spread can then be as much as several milliseconds. In all practical cases, however, time spreading is small enough that it does not cause significant smearing of CW keying or intersymbol interference in the slowly keyed modulations commonly used for digital EME.

Time spreading does have one very significant effect. Signal components reflected from different parts of the lunar surface travel different distances and arrive at Earth with random phase relationships. As the relative geometry of the transmitting station, receiving station and reflecting lunar surface changes, signal components may sometimes add and sometimes cancel, creating large amplitude fluctuations. Often referred to as *libration fading*, these amplitude variations will be well correlated over a *coherence bandwidth* of a few kHz, the inverse of the time spread.

9.3 Doppler Shift and Frequency Spread

EME signals are also affected by Doppler shifts caused by the relative motions of Earth and Moon. Received frequencies may be higher or lower than those transmitted; the shift is proportional to frequency and to the rate of change of total path length from transmitter to receiver. The velocities in question are usually dominated by the Earth's rotation, which at the equator amounts to about 460 m/s. For the self-echo or "radar" path, frequency shift will be maximum and positive at moonrise, falling through zero as the Moon crosses the local meridian (north-south line) and a maximum negative value at moonset. The magnitude of shifts depends on station latitude, the declination of the Moon and other geometrical factors. For two stations at different geographic locations the mutual Doppler shift is the sum of the individual (one-way) shifts. Maximum values are around 440 Hz at 144 MHz, 4 kHz at 1296 MHz and 30 kHz at 10 GHz. (See the article by Al Katz, K2UYH, "Devilish Doppler" in the online supplemental material for more information on Doppler shift and its effect on EME communications.)

Just as different reflection points on the lunar surface produce different time delays, they also produce different Doppler shifts. The Moon's rotation and orbital motion are synchronized so that approximately the same face is always toward Earth. The orbit is eccentric, so the orbital speed varies; since the rotation rate does not vary, an observer on Earth sees an apparent slow "rocking" of the Moon, back and forth.

Further aspect changes are caused by the 5.1° inclination between the orbital planes of Earth and Moon. The resulting total line-of-

sight velocity differences are around 0.2 m/s, causing a *frequency spread* of order 0.2 Hz at 144 MHz. Like all Doppler effects, these shifts scale with frequency. However, measured values of frequency spread increase slightly more rapidly than frequency to the first power because a larger portion of the lunar surface contributes significantly to echo power at higher frequencies. Linear scaling would suggest frequency spread around 15 Hz at 10 GHz, but measurements show it to be several times larger.

From a communication engineering point of view, libration fading is just another example of the so-called Rayleigh fading observed on any radio channel that involves multiple signal paths — such as ionospheric skywave, tropospheric scatter and terrain multipath channels with reflections from buildings, trees or mountains. Interference effects that cause signal fading depend on frequency spread as well as time spread. Signal amplitudes remain nearly constant over a coherence time given by the inverse of frequency spread. In general, fading rates are highest (shortest coherence times) when the Moon is close to the local meridian and lowest near moonrise and moonset. They also depend on the Moon's location in its elliptical orbit.

Typical coherence times are several seconds at 144 MHz, a few tenths of a second at 1296 MHz and 20 ms at 10 GHz. At 144 MHz. intensity peaks lasting a few seconds can aid copy of several successive CW characters, but at 432 MHz the timescale of peaks and dropouts is closer to that of single characters. At 1296 MHz the fading rates are often such that CW characters are severely chopped up, with dashes seemingly converted to several dits; while the extremely rapid fading at 10 GHz can give signals an almost "auroral" tone. Skilled operators must learn to deal with such effects as best they can. As described further below, modern digital techniques can use message synchronization as well as error-correcting codes and other diversity techniques to substantially improve the reliability of copy on marginal, rapidly fading EME signals.

9.4 Atmospheric and Ionospheric Effects

Propagation losses in the Earth's troposphere are negligible at VHF and UHF, although rain attenuation can be an important factor above 5 GHz. Tropospheric ducting of the sort that produces enhanced terrestrial propagation can bend signals so that the optimum beam heading for EME is directed away from the Moon's center. Even under normal conditions, enough refraction occurs to allow radio echoes when the Moon is slightly below the visible horizon. In practice, these problems are usually overshadowed by other

complications of doing EME at very low elevations, such as blockage from nearby trees or buildings, increased noise from the warm Earth in the antenna's main beam and manmade interference.

The Earth's ionosphere causes several propagation effects that can be important to EME. These phenomena depend on slant distance through the ionospheric layer, which increases at low elevations. At elevation 10°, attenuation through the daytime ionosphere is generally less than 0.5 dB at 144 MHz, and nighttime values are at least 10 times lower. These numbers scale inversely as frequency squared, so ionospheric absorption is mostly negligible for EME purposes. Exceptions can occur at 50 MHz, and under disturbed ionospheric conditions at higher frequencies. Ionospheric refraction can also be important at 50 MHz, at very low elevations. Ionospheric scintillations (analogous to the "twinkling" of stars in the Earth's atmosphere) can exhibit significant effects at VHF and UHF, primarily on EME paths penetrating the nighttime geomagnetic equatorial zone or the auroral regions. Again, disturbed ionospheric conditions magnify the effects. The multipath time spread is very small, less than a microsecond, while frequency spread and fading rate can be in the fractional hertz to several hertz range. These scintillations can increase the fading rates produced by Earth rotation and lunar

Much more important is the effect of Faraday rotation in the ionosphere. A linearly polarized wave will see its plane of polarization rotate in proportion to the local free-electron density, the line-of-sight component of the Earth's magnetic field and the square of wavelength. The effect is therefore greatest during the daytime, for stations well away from the equator, and at low frequencies. A mismatch $D\theta$ between an incoming wave's polarization angle and that of the receiving antenna will attenuate received signal power by an amount $\cos^2 D\theta$. As shown in **Figure 62**, polarization losses increase rapidly when the misalignment exceeds 45° .

Because of the 12 dependence, Faraday rotation is generally important for EME operation only at 432 MHz and below. The effect is cumulative for an outgoing signal and its returning echo, so a station transmitting and receiving with the same linearly polarized antenna will see its own echoes disappear whenever the total Faraday rotation is close to an odd integral multiple of 90°. Faraday rotation in the daytime ionosphere can amount to as much as a full turn at 432 MHz and many turns at 144 MHz. At 432 MHz the rotation may be essentially constant over several hours; on lower bands significant changes can occur in 30 minutes or less. Variations are especially noticeable near sunrise or sunset at one end of the path, where ionization levels

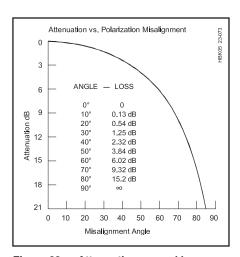

Figure 62 — Attenuation caused by misalignment of a linearly polarized signal with the polarization angle of a receiving antenna. The attenuation increases rapidly for alignment errors greater than 45°.

are changing rapidly.

The Earth's spherical shape determines the orientation in space of a wave emitted or received by an antenna with horizontal (or other locally referenced) polarization angle. As discussed in detail below, when combined with Faraday rotation this effect can cause users of fixed-linear-polarization antennas to experience apparent one-way propagation.

A polarized radio signal reflected from the Moon's rough surface is partially scattered into other polarization states, and a disturbed ionosphere can sometimes generate a mixture

of polarization angles. As a consequence, fading caused by 90° polarization misalignments will not always produce deep nulls. Measurements show that at UHF and below, the cross-polarized scattered signal is usually 15 dB or more below the principal polarization. On the other hand, at 10 GHz and higher, where the lunar surface is much rougher in terms of wavelength, cross-polarized diffuse echoes may be only a few dB below the principal reflected polarization. These comments apply to both linear and circular polarization.

10 Fundamental Limits

10.1 Background Noise

EME signals are always weak, so considerations of signal-to-noise ratio are paramount. (Noise is also discussed in the RF Techniques chapter.) A received signal necessarily competes with noise generated in the receiver as well as that picked up by the antenna, including contributions from the warm Earth, the atmosphere, the lunar surface, the diffuse galactic and cosmic background and possibly the sun and other sources. (Refer to Figure 61, and think of adding a warm atmosphere just above the Earth, the sun somewhere beyond the Moon, and galactic and extragalactic noise sources at even greater distances, filling the whole sky.) If P_n is the total noise power collected from all such noise sources expressed in dBW, we can write the expected signal-tonoise ratio of the EME link as

$$SNR = P_r - P_n = P_t + G_t + L + G_r - P_n$$
 (5)

Since isotropic path loss L is essentially fixed by choice of a frequency band (Table 7), optimizing the signal-to-noise ratio generally involves trade-offs designed to maximize $P_{\rm r}$ and minimize $P_{\rm n}$ — subject, of course, to such practical considerations as cost, size, maintainability and licensing constraints.

It is convenient to express P_n (in dBW) in terms of an equivalent system noise temperature T_s in kelvins (K), the receiver bandwidth B in Hz and Boltzmann's constant $k = 1.38 \times 10^{-23}$ J K⁻¹:

$$P_{n} = 10 \log (kT_{s}B) \tag{6}$$

The system noise temperature may in turn be written as

$$T_{s} = T_{r} + T_{a} \tag{7}$$

Here T_r is receiver noise temperature, related to the commonly quoted noise figure (NF) in dB by

$$T_{\rm r} = 290 \, (10^{0.1\rm NF} - 1) \tag{8}$$

Antenna temperature T_a includes contributions from all noise sources in the field of view, weighted by the antenna pattern. The lunar surface has a temperature around 210 K; since most antennas used for amateur EME

have beamwidths greater than the Moon's angular size, as well as sidelobes, the Moon's effect will be diluted and noise from other sources will also be received. Sidelobes are important, even if many dB down from the main beam, because their total solid angle is large and therefore they are capable of collecting significant unwanted noise power.

At VHF the most important noise source is diffuse background radiation from our Galaxy, the Milky Way. An all-sky map of noise temperature at 144 MHz is presented in the top panel of **Figure 63**. This noise is strongest along the plane of the Galaxy and toward the galactic center. Galactic noise scales as frequency to the –2.6 power, so at 50 MHz the temperatures in Figure 63 should be multiplied by about 15, and at 432 divided by 17. At 1296 MHz and above galactic noise

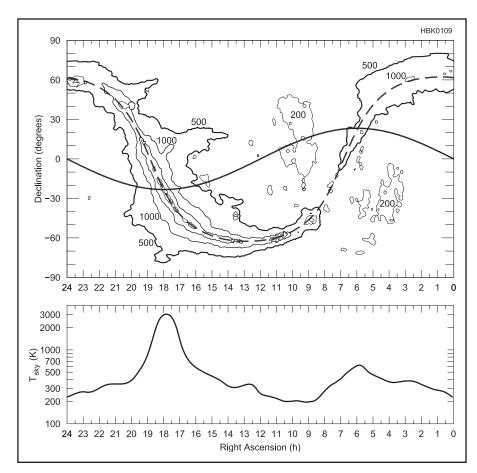

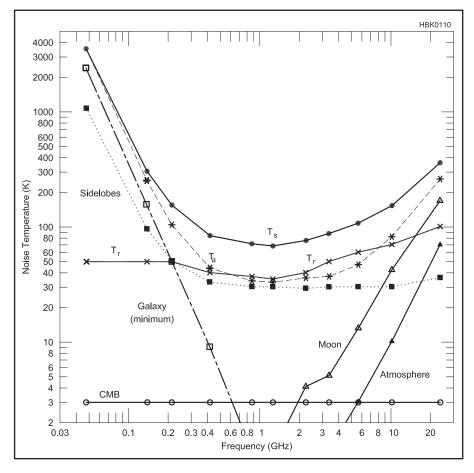

Figure 63 — *Top:* All-sky contour map of sky background temperature at 144 MHz. The dashed curve indicates the plane of our Galaxy, the Milky Way; the solid sinusoidal curve is the plane of the ecliptic. The Sun follows a path along the ecliptic in one year; the Moon moves approximately along the ecliptic (± 5°) each month. Map contours are at noise temperatures 200, 500, 1000, 2000 and 5000 K. *Bottom:* One-dimensional plot of sky background temperature at 144 MHz along the ecliptic, smoothed to an effective beamwidth 15°.

is negligible in most directions. During each month the Moon follows a right-to-left path lying close to the ecliptic, the smooth solid curve plotted in Figure 63. Sky background temperature behind the Moon therefore varies approximately as shown in the lower panel of Figure 63, regardless of geographical location on Earth. For about five days each month, when the Moon is near right ascension 18 hours and declination –28°, VHF sky background temperatures near the Moon are as much as 10 times their average value, and conditions for EME on the VHF bands are poor.

By definition the Sun also appears to an observer on Earth to move along the ecliptic, and during the day solar noise can add significantly to P_n if the Moon is close to the sun or the antenna has pronounced sidelobes. At frequencies greater than about 5 GHz the Earth's atmosphere also contributes significantly. An ultimate noise floor of 3 K, independent of frequency, is set by cosmic background radiation that fills all space. A practical summary of significant contributions to system noise temperature for the amateur bands 50 MHz through 24 GHz is presented in **Table 8** and **Figure 64** and **Figure 65**, discussed in the next section.

Figure 64 — Typical contributions to system noise temperature $T_{\rm s}$ as function of frequency. See text for definitions and descriptions of the various sources of noise.

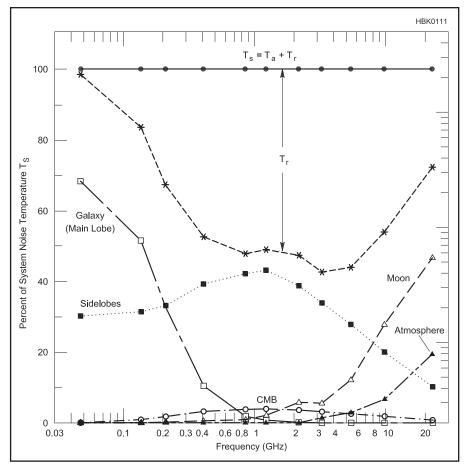

Figure 65 — Percentage contributions to system noise temperature as a function of frequency.

10.2 Antenna and Power Requirements

The basic circumstances described so far ensure that frequencies from 100 MHz to 10 GHz are the optimum choices for EME and space communication. Over this region and a bit beyond, a wide variety of propagation effects and equipment requirements provide a fascinating array of challenges and opportunities for the EME enthusiast. The enormous path-loss variability encountered in terrestrial HF and VHF propagation does not occur in EME work, and some of the remaining, smaller variations — for example, those arising from changing lunar distance and different sky background temperatures — are predictable. We can therefore estimate with some confidence the minimum antenna sizes and transmitter powers required for EME communication on each amateur band.

The necessary information for this task is summarized in Table 8 and Figures 64 and 65. Columns 2 through 6 of the table give typical contributions to system noise temperature from the cosmic microwave background (CMB), the Earth's atmosphere, the warm surface of the Moon, galactic noise

entering through the main antenna beam and sky and ground noise from an antenna's side and rear lobes. Antenna temperature T_a is a combination of all these contributions, appropriately weighted by antenna pattern; the system noise temperature T_s is then the sum of T_a and receiver noise temperature T_r , referred to the antenna terminals. Numbers in Table 8 are based on the fundamentals described in the previous section and on hypothetical antennas and receivers that conform to good amateur practice in the year 2009; they have been rounded to two significant figures. It is possible to do slightly better than these numbers—for example, by building antennas with lower sidelobe response or preamplifiers with still lower noise figure — but it's not easy!

The topmost curve in Figure 64 illustrates clearly why the frequency range from 100 MHz to 10 GHz is optimum for EME communication. Figure 65 shows that further reductions of T_s must come from lower T_r or better suppression of antenna sidelobes. There is nothing you can do about noise from the CMB, atmosphere, Moon or Galaxy entering your main beam! For comparison, the

very best professional receiving equipment achieves system noise temperatures around 20 K in the 1-2 GHz region — only a few dB better than current amateur practice. These systems generally use cryogenic receivers and very large dish antennas that can provide better suppression of sidelobes.

Having established reasonable target figures for system noise temperature, we can now proceed to estimate minimum antenna and power requirements for an EME-capable station on each amateur band. Rearrangement of Equations (5) and (6) yields the following relation for transmitter power P_t in dBW:

$$P_t = SNR - G_t - G_r - L + 10 \log (kT_sB)$$
 (9)

Values for L and T_c can be taken for each amateur band from Tables 7 and 8. For illustrative purposes let's assume SNR = 3 dB and B = 50 Hz, values appropriate for a good human operator copying a marginal CW signal. (The 50 Hz effective bandwidth may be established by an actual hardware or software filter, or more commonly by the operator's "ear-and-brain" filter used toget her with a broader filter in the transceiver.) For antennas we shall assume bays of four long Yagis for the 50 through 432 MHz bands, parabolic dishes of diameter 3 m on 1296 and 2304 MHz and 2 m dishes on the higher bands. Representative gains and half-power beamwidths for such antennas are listed in columns 3 and 4 of Table 9. Column 5 then gives the necessary transmitter power in watts, rounded to two significant figures.

A station with these baseline capabilities should be self sufficient in terms of its ability to overcome EME path losses — and thus able to hear its own EME echoes and make CW contacts with other similarly equipped EME stations. Note that the quoted minimum values of transmitter power do not allow for feed line losses; moreover, a CW signal with

Table 9
Typical Antenna and Power
Requirements for CW EME

Freq	Ant	G	HPBW	TxPwr
(MHz)	Type ¹	(dBi)	(deg)	(W)
50	4×12 m	19.7	18.8	1200
144	4×6 m	21.0	15.4	500
432	4×6 m	25.0	10.5	250
1296	3 m	29.5	5.5	160
2304	3 m	34.5	3.1	60
3456	2 m	34.8	3.0	120
5760	2 m	39.2	1.8	60
10368	2 m	44.3	1.0	25

¹Example antennas for 50, 144 and 432 MHz are Yagi arrays with stated lengths; those for 1296 MHz and higher are parabolic dishes of specified diameter. SNR = 3 dB in 50 Hz bandwidth hardly represents "armchair copy." At the highest frequencies, issues of oscillator stability and Doppler spreading might make the assumed 50 Hz bandwidth unrealistically narrow, thus requiring somewhat more power or a larger antenna. On the other hand, lower power and smaller antennas can be sufficient for working stations with greater capabilities than those in the table.

Other factors can reduce the minimum power or antenna gains required for successful EME, at least some of the time. One possibility, especially effective at 50 and 144 MHz at low moon elevations, is to take advantage of reflections from reasonably smooth ground (or better still, water) in front of your antenna. Often referred to as *ground gain*, these reflections can add as much as 6 dB to an antenna's effective gain at elevations where the reflections are in phase with the direct signal. Another possibility is to use more efficient coding and modulation schemes than provided by Morse coded CW.

10.3 Coding and Modulation

International Morse code with on-off keying (OOK) is an excellent general purpose communication mode. It is easy to implement and performs well in weak-signal conditions. EME operating procedures for CW usually include multiple repetitions so that essential parts of a bare-minimum QSO can be assembled from fragments copied on signal peaks. However, modern communication theory points the way toward modulation schemes significantly more efficient than OOK, codes better than Morse, and error-control methods more effective than simple repetition. Amateur experiments with these ideas have led to the current popularity of digital EME on the VHF, UHF, and microwave bands. In general, an efficient digital mode designed for basic communication with weak signals will compress user messages into a compact form and then add redundancy in the form of a mathematically defined error-correcting code (ECC). Such codes can ensure that full messages are recoverable with high confidence, even when significant portions of a transmission are lost or corrupted.

A number of distinct sources may contribute to the improved performance of such a mode over CW. Multitone FSK (MFSK) is a more efficient modulation than OOK, in part because each received symbol is roughly the equivalent of a full character, rather than a single dot or dash. For equivalent messages, MFSK can therefore be keyed much more slowly than CW and detected in a much smaller bandwidth. Morse code is self-synchronizing at the character level (if a signal is strong enough for letters to be recognized), but a Morse transmission contains no use-

ful information for synchronizing a whole message. This fact makes it difficult to piece together copied fragments of a CW message being sent repeatedly. As discussed later in the Operating Procedures section, K1JT's software package WSJT-X includes several MFSK modes for low SNR communications on HF and VHF/UHF/microwaves. More information is available in the Digital Protocols and Modes chapter and at physics.princeton. edu/pulsar/k1jt/wsjt.html. Also see the sidebar later in this chapter, "Computing and Internet Resources for EME."

In contrast, a synchronized digital transmission with ECC can encode the complete message into a new data format designed to enhance the probability that successful decoding will produce the message's full information content, with everything in its proper place. For the limited purpose of exchanging call signs, signal reports and modest amounts of additional information, digital EME contacts can be made at signal levels some 10 dB below those required for CW, while at the same time improving reliability and maintaining comparable or better rates of

Figure 66 — The 12-element Yagi used by DL1VPL to complete DXCC on 144 MHz.

Figure 67 — TF/DL3OCH used a rural road sign to help him give contacts with Iceland to a number of EME operators on 1296 MHz. Bodo has activated many DXCC entities on 1296 MHz EME by using JT65, a single long Yagi and a 100 W solid state amplifier.

Figure 68 — The portable EME-capable 10 GHz station of VK7MO, set up at roadside in the Australian outback.

information throughput. Depending on your skill as a CW operator, the digital advantage may be even larger.

Thus, digital EME contacts are possible between similar stations with about 10 dB less power than specified in Table 9, or with 5 dB smaller antenna gains at both transmitter and receiver. Examples of antennas for three small but very effective EME

stations are shown in **Figures 66** to **68**. Figure 66 shows the single 12-element Yagi used by Thomas, DL1VPL, to complete his DXCC on 144MHz. Figure 67 shows the highly portable EME setup of Bodo, DL3OCH. With a single long Yagi (59 elements, 5 m boom, 21.8 dBi gain), a 100 W solid state power amplifier (SSPA) and the JT65C digital mode, ¹ this equipment has helped him to

provide dozens of new DXCC credits on 1296 MHz from countries with little or no regular EME activity. Figure 68 shows the 10 GHz portable station of Rex, VK7MO. It includes a 10 GHz transverter, a 50 W SSPA, and a 2.5-foot (75 cm) dish mounted on a collapsible tripod. Rex has made hundreds of EME contacts with this equipment using the JT4 and QRA64 digital modes.

11 Building an EME Station

11.1 Antennas

The antenna is arguably the most important element in determining an EME station's capability. It is not accidental that the baseline station requirements outlined in Table 9 use Yagi arrays on the VHF bands and parabolic dishes at 1296 MHz and above: one of these two antenna types is almost always the best choice for EME. The gain of a modern, well designed Yagi of length ℓ can be approximated by the equation

$$G = 8.1 \log (\ell / \lambda) + 11.4 dBi$$
 (10)

and stacks of Yagis can yield close to 3 dB (minus phasing line losses) for each doubling of the number of Yagis in the stack.

For comparison, the gain of a parabolic dish of diameter d with a typical feed arrangement yielding 55% efficiency is

$$G = 20 \log (d/\lambda) + 7.3 dB$$
 (11)

The gains of some nominal antennas of each type are illustrated graphically in **Figure 69**, which helps to show why Yagis are nearly always the best choice for EME on the VHF bands. They are light, easy to build and have relatively low wind resistance. Stacks of four Yagis are small enough that they can be mounted on towers for sky coverage free of nearby obstructions. Larger arrays of 8, 16 or even more Yagis are possible, although the complexity and losses in phasing lines and power dividers then become important considerations, especially at higher frequencies. Long Yagis are narrowband antennas, usable on just a single band.

We usually think of the linear polarization of a transmitted signal as being "horizontal" or "vertical." Of course, on the spherical Earth these concepts have meaning only locally. As seen from the Moon, widely separated horizontal antennas may have very different orientations (see **Figure 70**). Therefore, in the absence of Faraday rotation an EME signal transmitted with horizontal polarization by station A will have its linear polarization misaligned at stations B and C by angles known as the *spatial polarization offset*. In Figure 70 the signal from A arrives with vertical

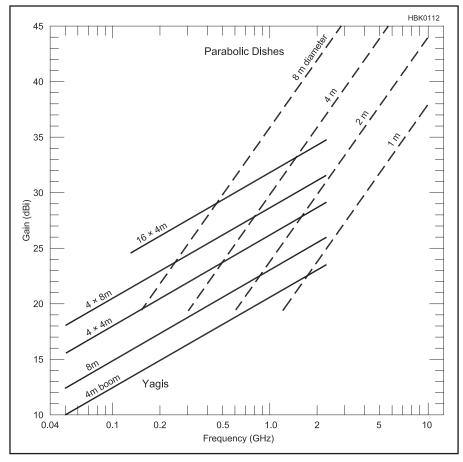

Figure 69 — Representative gains of practical Yagi antennas, arrays of Yagis and parabolic dishes as a function of frequency. Yagi arrays make the most cost-effective and convenient antennas for EME on the VHF bands, while parabolic dishes are generally the best choice above 1 GHz.

polarization at B and at 45° to the horizon at C. Suppose C is trying to work A and $q_s = 45^\circ$ is the spatial polarization offset from A to C. The return signal from C to A will be offset in the opposite direction, that is, by an amount $-q_s = -45^\circ$. The Faraday rotation angle θ_F , on the other hand, has the same sign for transmission in both directions. Thus the net polarization shift from A to C is $\theta_F + q_s$, while that from C to A is $\theta_F - q_s$. If θ_F is close to any of the values $\pm 45^\circ$, $\pm 135^\circ$, $\pm 225^\circ$, ..., then one of the net polarization shifts is nearly 90° while the other is close to 0°. The result for

stations with fixed linear polarization will be apparent one-way propagation: for example, A can copy C, but C cannot copy A.

Obviously no two-way contact can be made under these conditions, so the operators must wait for more favorable circumstances or else implement some form of polarization control or polarization diversity. One cost-effective solution is to mount two full sets of Yagi elements at right angles on the same boom. Arrays of such cross-polarized or "Xpol" Yagis make especially attractive EME antennas on the VHF and lower UHF bands because they

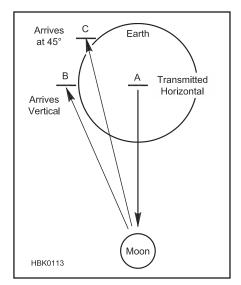

Figure 70 — The spherical Earth creates spatial polarization offsets for well-separated stations with horizon-oriented linear polarization. Here, a signal transmitted horizontally at A arrived with vertical polarization at B and midway between horizontal and vertical at C. When combined with Faraday rotation, offsets close to 45° can lead to apparent one-way propagation. See text for details.

offer a flexible solution to the linear-polarization misalignment problem. As an example, **Figure 71** shows the 4×10 element, dual-polarization EME array at KL7UW. This antenna has accounted for many hundreds of EME contacts with the state of Alaska on 2 meters.

At 1296 MHz and above, gains of 30 dBi and more can be achieved with parabolic dishes of modest size. As a result, these antennas are almost always the best choice on these bands. Their structure does not depend on any radio frequency resonances, so in many ways dishes are less critical to build than Yagis. Element lengths in high-gain Yagis must be accurate to better than 0.005λ , while the reflecting surface of a dish need be accurate only to about 0.1 \(\lambda \). Mesh surfaces are attractive at frequencies up to at least 5 GHz, because of their light weight and lower wind resistance. Openings in the mesh can be as large as 0.05 λ without allowing much ground noise to feed through the surface. A parabolic antenna has a single feed point, so there are no losses in phasing lines or power splitters. You can use a dish on several bands by swapping feeds, and with suitable feed designs you can produce either linear or circular polarization, including dual polarizations. A very attractive and convenient option is to transmit in one sense of circular polarization and receive in the opposite sense. Transmitting in right-hand circular (RHC) and receiving in LHC has become the standard for EME on bands from 1296 MHz up to 5.7 GHz. Linear polarization is still used

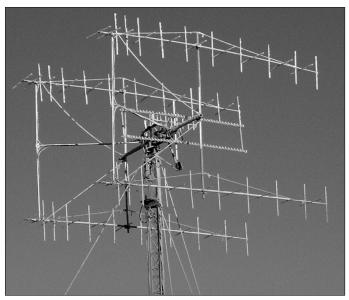

Figure 71 — Array of four 10-element, dual-polarization 144 MHz Yagis at KL7UW. Alaskan frost makes the horizontal and vertical elements stand out clearly. A pair of loop Yagis for 1296 MHz can be seen inside the 2 meter array.

most commonly for EME at 10 and 24 GHz.

As made clear in Figure 69, the 432 MHz band lies in a transition region where both Yagis and parabolic dishes have attractive features. Either four long Yagis or a 6 m dish can produce enough gain (about 25 dBi) to let you work many other EME stations on this band. Many linear-polarization systems are already in use — for good reason, since most amateur use of this band is for terrestrial communication — so converting everyone to circular polarization is impractical. Therefore, schemes have been devised to physically rotate dish feeds and even whole Yagi arrays to cope with the resulting polarization alignment problems. Another scheme is to use a dualpolarization dish feed or dual-polarization Yagis, as described above and increasingly used on 144 MHz. This approach has not gained wide popularity on 432 MHz, mainly because at this wavelength it is hard to find room for the feedlines and matching system at the antenna feed points. One successful implementation is shown in **Figure 72**.

ANTENNA PATTERN

A clean pattern with good suppression of side and rear lobes is important for all EME antennas—especially at 432 MHz and above, where excessive noise pickup through sidelobes can significantly increase T_s . For Yagi arrays you should use modern, computer-optimized designs that maximize G/T_s , the ratio of forward gain to system noise temperature. Be sure to pay attention to maintaining a clean pattern when stacking multiple antennas. First sidelobes within 10- 15° of the main beam may not be a major problem, because their solid angle is small and they will look mostly at cold sky when EME conditions are favorable.

Side and rear lobes farther from the main beam should be suppressed as much as possible, however. Remember that even close-in sidelobes will degrade your receiving performance at low elevations.

For parabolic dishes, G/T_s is optimized by using a feed with somewhat larger taper in illumination at the edge of the dish than would yield the highest forward gain. Best forward gain is generally obtained with edge taper around $-10 \, dB$, while best G/T_s occurs around $-15 \, dB$. Edge taper of $-12 \, dB$ is usually a good compromise. Some good reproducible designs for dish feeds are described in references at the end of this section.²

ANTENNA MOUNTS

EME antennas have high gain and narrow main beams that must be properly aimed at the Moon in two coordinates. Although polar mounts (one axis parallel to the Earth's axis) have sometimes been used, by far the most popular mounting scheme today is the elevation-over-azimuth or *az/el* mount. Readily available computer software (see the sidebar, "Computer and Internet Resources for EME") can provide azimuth and elevation coordinates for the Moon, and a small computer can also control antenna positioning motors to automate the whole pointing system.

For mechanical reasons it is desirable to place the antenna's center of gravity close to the intersection of the vertical (azimuth) and horizontal (elevation) axes. On the other hand, the mounting structure must not interfere with critical active regions of the antenna. Stacked Yagis are generally mounted so that metallic supporting members are perpendicular to the radiating elements or located at midpoints where the effective apertures of separate Ya-

Figure 72 — Dual-polarization EME array at W2PU. At the left, shows the four 15-element, rear-mounted Yagis. Boom length is 3.5 m, and stacking distance is 1.2 m in each direction. The right photo is a close-up showing some details around the driven loops.

Figure 73 — This 3 m TVRO dish with aluminum frame and mesh surface was outfitted for 1296 MHz EME as a joint effort by VA7MM and VE7CNF. The dual-circular polarization feed is a VE4MA/W2IMU design.

Figure 74 — Mounting arrangement, counterweights and az/el control system for the VA7MM 3 m dish.

gis meet. Feed lines and conducting support members must not lie in the active planes containing Yagi elements, unless they run wholly along the boom. For dual-polarization Yagis, feed lines should be routed toward the rear of each Yagi and any mid-boom support members must be non-conducting. For EME there is nothing magical about using horizontal and vertical for the two orthogonal polarizations, and there are some advantages to mounting cross-Yagis with elements in the "x" rather than "+" orientation.³

Parabolic dishes are usually mounted from

behind, with counterweights extending rearward to relieve torque imbalance on the elevation axis. Screw-jack actuators designed for positioning 1980s-style TVRO dishes can be readily adapted for elevation control.⁴ Standard heavy-duty antenna rotators can be used for azimuth positioning of dishes up to about 3 m in size. Larger dishes may require heavier, one-of-a-kind designs for pointing control. **Figures 73** through **75** show examples of parabolic dishes in the 2-3 m range, neatly and successfully outfitted for EME at VA7MM and N4MW.

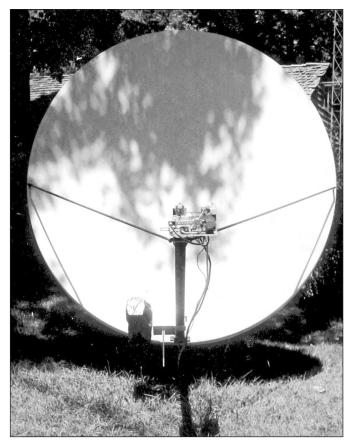

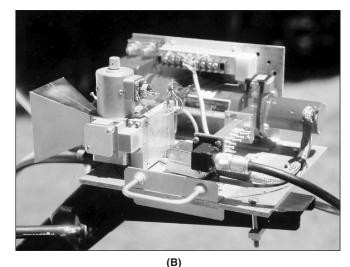

Figure 75 — N4MW outfitted this 2.6 m offset parabolic dish for 10 GHz EME. Equipment mounted at the focus (close-up at B) includes low noise preamplifier, transverter, traveling wave tube (TWT) power amplifier and feed horn for 10 GHz.

11.2 Feed lines, Preamplifiers and TR Switching

Any feed line between the antenna and receiver introduces attenuation and noise, so at UHF and above it is vital that the lownoise preamplifier (LNA) be mounted very close to the antenna terminals. At ambient temperature, every 0.1 dB of loss in front of the LNA adds at least 7 K to the effective T_r , and therefore to T_s . On bands where T_a is much lower than ambient, even 0.1 dB of attenuation can result in 0.5 dB loss of receiver sensitivity.

LNA gain should be sufficient to overcome feed line losses and dominate the noise contributed by subsequent stages by at least 15-20 dB. Current practices usually employ one or, especially at 432 MHz and above, two low-noise GaAsFET or HEMT transistors in the preamplifier, with only a simple noise impedance matching circuit between the first active device and the antenna. Only if severe out-of-band interference is present should a narrow filter be placed ahead of the first LNA. Bandpass filtering is often desirable between LNA stages, and may be used without significant impact on system noise temperature. The feedhorn of a dish antenna can have a valuable high-pass effect that attenuates signals at lower frequencies.

The same antenna is generally used for both transmitting and receiving, so the LNA must be out of the line and protected when transmitting. Figure 76A illustrates a preferred switching arrangement that uses two separate feed lines: a low-loss line to carry transmitter power and a relatively inexpensive feed line from LNA to receiver. A high-power relay K1 at the antenna handles TR switching; a second relay, K2, may be used to protect the LNA in case the isolation at K1's receive port is inadequate.

Additional relays are required in order to make best use of a dual-linear-polarization system. Figure 76B shows an arrangement that lets you select either horizontal or vertical polarization for transmitting (via relay K5) and use both polarizations simultaneously for receiving. A dual-channel receiver can form a linear combination of signals in the two channels to match the polarization of a desired signal exactly, whatever its angle. Such optimization is readily accomplished in a receiver whose last stages are defined and implemented in software, as in the highly effective *Linrad* system designed by SM5BSZ.⁵ For digital EME using dual-polarization antennas, Linrad and a software program called MAP65 make an especially powerful combination.6

With circular polarization you may not need a high-power TR relay at all. Figure 76C shows a typical arrangement with transmitter connected to one port of a feed horn providing both senses of circular polarization, and the LNA to the other port. Since the isolation between ports may be only 20 or 30 dB, a low-power relay protects the LNA during transmit periods. In all of these schemes, suitable sequencing should be used to assure that the LNA is disconnected before transmission can begin. Many amateurs find it best to use the energized position of TR relays on receive. When the station is not in use, preamplifiers will then be disconnected from the antenna.

11.3 Transmitters and Power Amplifiers

FREQUENCY STABILITY

Weak signals are best detected in a bandwidth no wider than the signal itself. As a consequence, EME systems must use stable oscillators. For best results with CW your frequency drift over a minute or so should be no more than 10 Hz at the operating frequency; with digital modes the ideal target may be several times smaller. Most modern transceivers are stable enough at VHF, but some only marginally so at UHF.

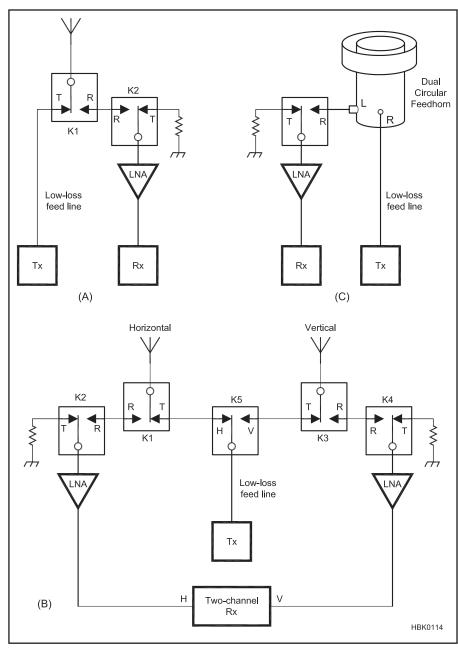

Figure 76 — Recommended "front ends" for EME systems include low-noise preamplifiers (LNAs) mounted at the antenna and use separate feed lines for transmitting and receiving. Relay K2 shown in (A) may be omitted if K1 provides adequate isolation of the LNA while transmitting. An arrangement like that in (B) is recommended for a dual-polarization antenna such as an array of cross-Yagis. Transmitter power is sent to one polarization or the other, but received signals in both polarizations are amplified and sent on to a dual-channel receiver. Part (C) shows a suitable arrangement for circular polarization implemented with a two-port, dual-circular-polarization feed horn. In this case, no high-power TR relay is required.

The crystal oscillators used in transverters may need temperature compensation for adequate stability; better still, they can be phase-locked to an external high-stability reference oscillator. Many successful EME QSOs have been made on the microwave bands using 5-10 W transmitter power and parabolic dishes smaller than 2 m (up to 5.7 GHz) and even 1 m (at 10 and 24 GHz). These are significantly

smaller systems than the baseline examples listed in Table 9. Such contacts generally depend on having stabilized local oscillators. Especially for digital EME, where detection bandwidths less than 10 Hz are used, unstable oscillators lead directly to loss of sensitivity.

POWER OUTPUT

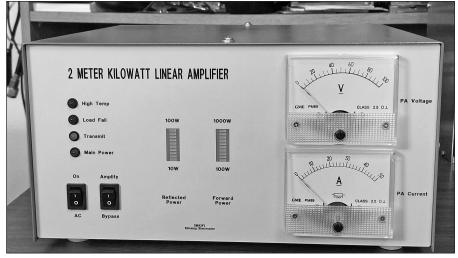

After frequency stability, the most impor-

tant specification for an EME transmitter is power output. The maximum power practically achievable by amateurs ranges from 1500 W on the VHF and lower UHF bands down to the 100 W range at 10 GHz. Fortunately, the required power levels for EME (Table 9) are compatible with these numbers. At 432 MHz and below, triode or tetrode vacuum tubes with external-anode construction can provide ample gain and power output. Some popular tubes include the 4CX250, 8930, 8874, 3CX800, 8877, GU-74B, GS-23B and GS-35B. Amplifiers using one or a pair of these (or other similar tubes) can provide output powers ranging up to 1000 or 1500 W on the 50 to 432 MHz bands. VHF and UHF power amplifiers based on solid state power devices have also become viable and attractive alternatives. Many amateurs have built solid-state power amplifiers (SSPAs) using these techniques, and commercial designs are available. Figure 77 shows a kilowatt amplifier for 2 m made by W6POL.7

At frequencies above 1 GHz, transit-time limitations and physical structures prevent most high-power vacuum tubes from performing well. For many years planar triodes in the 2C39/7289/3CX100 family were the mainstays of amateur 1296 MHz power amplifiers. These still work well, but today they are increasingly being replaced by SSPAs. As prices come down and power levels increase, these units are becoming more popular with EME operators. Surplus SSPAs usable on the 902, 2304 and 3456 MHz bands have been attractive buys in recent years, providing output power up to several hundred watts at reasonable cost. Two, four or even more units are sometimes used together to achieve higher output. SSPAs with at least 50 W output can be built and are available for the 5.7 and 10 GHz bands.

RF SAFETY

One final point must be made in a discussion of high power amplifiers. Anyone who has thought about how a microwave oven works should know why RF safety is an important issue. Dangerous levels of radio frequency radiation exist inside and at short distances from power amplifiers and antennas. In normal operation, power density is highest in the immediate vicinity of small, low-gain antennas such as feeds for parabolic dishes. EME operators should be aware that ERP (effective radiated power) can be highly misleading as a guide to RF hazards. Somewhat counter-intuitively, a large, high-gain antenna helps to reduce local RF hazards by distributing RF power over a large physical area, thus reducing power density. Be sure to read the RF Safety section in the Safety chapter and pay attention to the RF protection guidelines there.

(A)

12 Getting Started with EME

Perhaps you already have a weak-signal VHF or UHF station with somewhat lesser capabilities than those recommended in Tables 8 and 9, and would like to make a few EME contacts before possibly undertaking the task of assembling a "real" EME station. On 144 and 432 MHz — probably the easiest EME bands on which to get started — you can visually point your single long Yagi at the rising or setting moon and work some of the larger EME stations. Your daily newspaper probably lists the approximate times of moon rise and moon set in your vicinity; many simple web- or smartphone-based calculators can give you that information as well as the Moon's azimuth and elevation at any particular time (see the sidebar, "Computer and Internet Resources for EME").

These aids may be all you need to make your first EME contacts, especially if you take advantage of the weak-signal capabilities of an efficient digital mode. To optimize your chances of success, adapt your operating procedures to the prevailing standards that other EME operators will be using, as discussed below. For your first attempts you may want to make prearranged schedules with some established stations.

12.1 Tracking the Moon

For serious EME work you'll want a more general way of keeping your antenna pointed at the Moon. The Earth and Moon complete their mutual orbit every 27.3 days, one sidereal month. The lunar orbit is inclined to the plane of the ecliptic, the Earth-Sun orbital plane, by 5.1°. Since the Earth's equator is itself inclined at 23.5° to the ecliptic, the Moon's path through the sky swings north and south of the equator by as much as 28° in a monthly cycle (see Figure 63).

Predicting the Moon's exact position is a complicated problem in celestial mechanics, but is readily handled to sufficient accuracy by simple computer software. In general the problem can be reduced to 1) calculating the Moon's position on the sky, as seen by a hypothetical observer at the center of the Earth; 2) applying a parallax correction to yield the lunar position at a specified location on the Earth's surface; and 3) converting the astronomical coordinates of right ascension and declination to azimuth and elevation at the specified terrestrial location.

Of course, the Earth's rotation and Moon's orbital motion imply that the Moon's direction is constantly changing. Suitable computer software can follow these changes and generate the necessary commands to keep your antenna pointed at the Moon. Several free or inexpensive software packages with moon-tracking features are listed in the side-

bar, "Computer and Internet Resources for EME," and such facilities are built into the programs WSJT-X and MAP65 widely used for digital EME. For good results you should aim for pointing accuracies of 1/4 of your half-power beamwidth or better.

12.2 System Evaluation

Careful measurements of your EME system's performance can help to determine where station improvements can be made. Transmitter performance is essentially determined by power output, feed line losses and antenna gain. The first two can be measured in standard ways, but antenna gain is much more difficult. The most useful figure of merit for receiving performance is G/T_s, and while absolute measurements of either G or T_s separately are difficult, you can measure their ratio with useful accuracy and compare it with expectations. One technique particularly useful at 432 MHz and above is to use the sun as a broadband noise source. Point your antenna at cold sky and then at the sun, and

measure y, the ratio of received noise power in the two directions. Operate your receiver at maximum bandwidth with the AGC off, and if possible make the observations with the sun at elevation 30° or higher.

To calculate G/T_s from y, you will need a contemporaneous estimate of solar flux density at your operating frequency. Daily measurements of solar flux are obtained at a number of standard frequencies and made available online (see the sidebar, "Computer and Internet Resources for EME"); you can interpolate an approximate flux value for the amateur band in question. Solar flux densities vary with sunspot activity, and day-to-day or even hour-to-hour variations are especially large at lower frequencies and near solar maximum. Representative monthly median values for six frequencies are presented in Figure 78 over sunspot cycle 23. As a starting point, you can estimate a value of solar flux for your band and a similar point in the current sunspot cycle directly from Figure 78. Then, if S* is the solar flux density in units of W m-2 Hz-1 and y is expressed as a

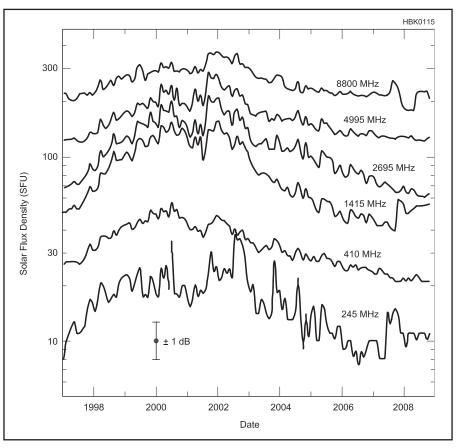

Figure 78 — Monthly median values of solar flux density at six frequencies, over the 11 years of solar cycle 23. Original data are from the Sagamore Hill Observatory in Massachusetts. At the lower frequencies, and especially near solar maximum, day-to-day and even hour-to-hour upward variations can be an order of magnitude larger than those in the monthly medians.

Table 10 Representative G/T_s and Y_{sun} for **Example Antennas**

Freq	Ant	G	G/T_s	Y_{sun}
(MHz)	Type ¹	(dBi)	(dB)	(dB)
144	4×6 m	21.0	-3.8	4
432	4×6 m	25.0	5.8	12
1296	3 m	29.5	11.1	11
2304	3 m	34.5	15.6	11
3456	2 m	34.8	15.3	9
5760	2 m	39.2	18.8	9
10368	2 m	44.3	22.4	11

¹Example antennas for 144 and 432 MHz are Yagi arrays with stated lengths; those for 1296 MHz and higher are parabolic dishes of specified diameter.

dimensionless ratio, the corresponding value of G/T_s in dB is given by

$$\frac{G}{(T_2^2)} = 10 \log \left(\frac{8\pi k (y-1)}{S^* \lambda^2} \right)$$

Solar flux is usually quoted in Solar Flux Units (1 SFU = 10^{-22} W m⁻² Hz⁻¹), and with S in those units Equation (12) can be reduced to the simpler relation

$$\frac{G}{(T_s^3)} = 10 \log \left(\frac{3.47 (y-1)}{S \lambda^2} \right)$$

Representative values of G/T_s and $Y_{sun} =$ 10 log y for the example antennas of Table 9 are given in columns 4 and 5 of Table 10. The tabulated values of Y_{sun} are based on quiet-sun flux densities typical of years near sunspot minimum.

Of course, receiving your own echoes from the Moon provides the best guarantee that your equipment is capable of EME communication with comparable stations. Transmitting a few dashes, then standing by to hear your lunar echo some 2.5 s later, brings a thrill that most hams never forget. With suitable signalprocessing software, echoes can be detected and measured even with relatively low-power equipment. Program WSJT-X (see the sidebar, "Computer and Internet Resources for EME") includes an automated echo-testing facility that is useful for quantitative measurements even if your echoes are many dB below the audible threshold.

12.3 Operating Procedures

The more that's known about likely structure, content and timing of a transmitted message, the easier it is to copy. EME signals are often near the threshold of readability, so it is highly desirable to standardize operating procedures and message structure, and to provide transmissions with enough redundancy

to capitalize on signal peaks and bridge likely gaps in reception.

You may wish to make your first EME QSOs with the aid of explicit schedules: that is, arrangements to attempt a contact with a particular station at a specified time and frequency. EME schedules usually state the duration of timed transmissions as well as starting time, transmitter frequency, and an indication of which station will transmit first. For a minimal QSO, message information is often reduced to the bare essentials of call signs, signal reports and acknowledgments. The signal report is sometimes reduced to a "yes or no" indication of whether both call signs have been successfully copied.

Remember to allow for Doppler shifts, especially at higher frequencies where the offset may exceed your received bandwidth. Most moon-tracking software used for EME can display the expected frequency shift for your own echoes as well as that for a distant station. In a scheduled QSO attempt, keep your transceiver set to the schedule frequency and use its RIT control to search for the other station around his expected Doppler shift. When looking for contacts at random, especially at 432 MHz and above, set your RIT to the expected Doppler shift of your own echoes. If a station you copy does likewise, you will find each other's signals on the same frequency as your own echoes. Many operators also benefit from using a software-driven panoramic spectral display of the "waterfall" variety, which can make signal acquisition much easier. The program WSJT-X, widely used for digital EME, can be configured to compensate for EME Doppler shifts automatically with most transceivers.

CW EME FORMAT

By convention, a minimal CW EME contact usually follows a format something like the sequence of messages in **Table 11**. If timed TR sequences are being used, the essential information is repeated for the full duration of a sequence.

The standard QSO procedures involve a number of different messages sent in sequence, and operators do not proceed to the next message until they have copied the essential information (call signs, signal report, acknowledgements) in previous messages. After call signs have been copied, a signal report is sent. Because CW dahs are easier to discern than dits, a default EME signal report (essentially meaning "I have copied both call signs") is the letter O. A station receiving call signs and O responds with RO, and a final acknowledgment of a valid contact is signified by sending RRR On 432 MHz and above, the letter M is sometimes used as an alternative signal report meaning "both call signs copied with difficulty." Of course, when

Table 11 Typical Messages in a Minimal EME **CW Contact**

Period	Message
1	CQ CQ CQ DE W6XYZ W6XYZ
2	W6XYZ DE K1ABC K1ABC
3	K1ABC DE W6XYZ 000 000
4	W6XYZ DE K1ABC RO RO RO
5	K1ABC DE W6XYZ RRR RRR
6	W6XYZ DE K1ABC TNX 73

signals are adequate for reasonably good copy normal RST signal reports can be used and other restrictions on message structure and timing relaxed.

In non-scheduled operation, it frequently happens (for example, in response to your CQ) that you can recognize and copy your own call more easily than the other station's call. The sequence YYY... (for "Your call") can be sent to ask a calling station to send his call only, repeating it many times. A contact is considered complete and valid when RRR has been received (after message number 5 in Table 11 has been received). However, at this point the other station does not know that his acknowledgment was copied, so it is normal to finish with something like message 6.

The conventional duration of transmit and receive periods is different on different bands and has evolved somewhat over time. On 50 and 144 MHz, stations usually transmit for one full minute and then receive for a full minute. On 432 MHz and above, schedules with 2.5-minute transmissions have been standard. The longer period gives stations with mechanically variable polarization adequate time to peak a received signal.

CW sending speed is generally around 12 to 15 WPM. Some operators find it helpful to use greater-than-normal spacing between complete letters. Keep in mind that characters sent too slowly may be chopped up by typical EME fading, while code sent too fast will be jumbled. When transmitting call sequences, send the other station's call once, followed by "DE" and your own call once or twice. Then pause and repeat the sequence. This cadence sets a rhythm so that the receiving operator can anticipate when the missing parts of a message can be expected to arrive. Send with proper spacing; the use of a programmable keyer or computer keyboard-to-Morse program is especially helpful and encouraged. A signal buried in the noise and accompanied by fading is hard enough to copy, without the added complication of irregular sending.

DIGITAL EME

Since 2003 most digital EME has been done using the JT65 protocol as implemented in computer programs WSJT, MAP65 and most recently WSJT-X (see the sidebar, "Com-

puter and Internet Resources for EME"). Like other popular digital modes, JT65 requires a personal computer with a sound card for audio input and output. It uses structured message formats, a Reed Solomon error-correcting code with slightly more than five-fold redundancy and 1-minute TR sequences. Signal peaks and dropouts due to multipath fading do not affect individual characters or words, but rather the probability of decoding the whole message. The modulation is 65-tone frequency shift keying (65-FSK) with computer-generated audio tones modulating a single-sideband transmitter in USB mode.

As expected from theory, results show that JT65 contacts can be made at signal levels more than 10 dB below those needed for CW. The detection bandwidth implemented in receiving software for JT65 is as small as 2.7

Hz. This may be compared with minimum bandwidths of order 50 Hz for 15 WPM CW.

The JT4 and QRA64 protocols use the same structured message formats and operating procedures as JT65. JT4 uses a convolutional error-correcting code and 4-FSK modulation. Submodes offer increasingly wide tone separations that can be especially helpful on paths with large Doppler spread. For example, JT4F (tone separation 157.5 Hz) is widely used for EME on 10 and 24 GHz. QRA64 is a recent new addition in WSJT-X. It uses a *Q-ary Repeat-Accumulate* code — a type of non-binary low-density parity-check code currently at the forefront of research in communication theory. As implemented in WSJT-X, submode QRA64A had been shown to be very effective for EME on 144 MHz, and QRA64D had become the preferred

mode for EME at 10 GHz.

Basic procedures for minimal contacts with any of these digital modes are similar to those for CW. Examples of typical message sequences are shown in Table 12. Standard messages include space reserved for Maidenhead grid locators, so this information is normally exchanged along with call signs. Following CW practice, you should proceed to the next message in the QSO sequence only when information from the previous step has been copied. In JT4 and JT65 a default signal report may be sent as OOO, but many operators prefer to send and receive numerical signal reports (giving the signal strength in dB, relative to noise power in a standard 2500 Hz bandwidth) as measured by the receiving software. Messages using such reports are shown in the final column of Table 12. Many additional details on the usage of the digital protocols can be found in documentation distributed with the WSJT-X program. Figure 79 shows an example screen shot with the messages exchanged in a QSO between NJ2R and K1JT via 144 MHz EME.

12.4 Finding QSO Partners

At the time of this writing (early 2017) levels of EME activity are highest on 144 MHz. Almost any time the Moon is above your horizon (excluding a few days each month when it is near the plane of the Milky Way), you can find JT65 EME signals in the frequency range 144.100 to 144.160 MHz — often dozens of them, especially on weekends. Hundreds of operators, worldwide, are "on the Moon" regularly using JT65 (and increasingly also QRA64) on 144 MHz. Some of the larger stations have made EME contacts with more than 2000 other stations. Operating frequencies of particular stations are often posted on real-time loggers and on the website LiveCQ (see the sidebar, "Computer and Internet Resources for EME"). Explicit schedules can also be made on the loggers, and this is a good way to initiate your first EME contacts. Don't compromise a true EME contact by communicating via the logger after a QSO attempt has been started, however.

CW activity on the 144 MHz band, as well as EME activity on higher bands in any mode, tends to be concentrated in activity weekends scheduled once each month when the Moon is in a favorable location. After 144 MHz, the bands with most EME activity are 1296 and 432 MHz. On those bands random CW (and occasionally SSB) activity is mostly found between 5 and 30 kHz above the nominal sub-band boundary (for example, between 1296.005 and 1296.030), and digital activity is between .060 and .090, concentrating around .065 or .070. A hundred or more stations are typically active on these bands during the annual ARRL International EME

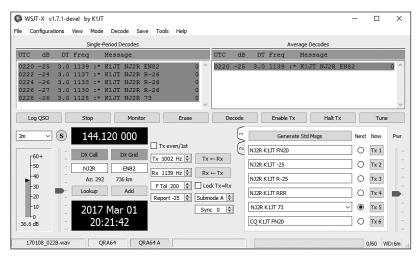

Figure 79 — Screen shot of computer program WSJT-X showing an EME QSO on 2m between K1JT and NJ2R, using the QRA64 protocol.

Competition and in other major operating events

The higher microwave bands 2.3 through 10 GHz have at least several dozen regularly active stations. On these and higher bands activity tends to concentrate around .100. Keep in mind that different band segments may be assigned in different parts of the world.⁸ For example, North American stations use 2304.100, but some Europeans work around 2320.100. EME activity on the 50, 222 and 902 MHz bands is mostly done with prearranged schedules. The sidebar, "Computer and Internet Resources for EME" lists some resources that can help you to find schedule partners and the dates of EME contests and activity weekends.

14 Glossary of Space Communications Terminology

- AMSAT A registered trademark of the Radio Amateur Satellite Corporation, a nonprofit scientific/educational organization located in Washington, DC. It builds and operates Amateur Radio satellites and has sponsored the OSCAR program since the launch of OSCAR 5. (AMSAT, 10605 Concord St, #304, Kensington, MD 20895; www.amsat. org)
- Anomalistic period The elapsed time between two successive perigees of a satellite.
- Antenna temperature Used in EME system evaluation, a measure of the noise picked up by the antenna from all noise sources in the field of view, weighted by the antenna pattern.
- AO-# The designator used for AMSAT OSCAR spacecraft in flight, by sequence number.
- AOS—Acquisition of signal. The time at which radio signals are first heard from a satellite, usually just after it rises above the horizon.
- **Apogee** The point in a satellite's orbit where it is farthest from Earth.
- Argument of perigee The polar angle that locates the perigee point of a satellite in the orbital plane; drawn between the ascending node, geocenter, and perigee; and measured from the ascending node in the direction of satellite motion.
- Ascending node The point on the ground track of the satellite orbit where the sub-satellite point (SSP) crosses the equator from the Southern Hemisphere into the Northern Hemisphere.
- Az-el mount An antenna mount that allows antenna positioning in both the azimuth and elevation planes.
- Azimuth Direction (side-to-side in the horizontal plane) from a given point on Earth, usually expressed in degrees. North = 0° or 360°; East = 90°; South = 180°; West = 270°.
- Circular polarization (CP) —Describes an electromagnetic wave in which the electric and magnetic fields are rotating. If the electric field vector is rotating in a clockwise sense, then it is called right-hand circular polarization and if the electric field is rotating in a counterclockwise sense, it is called left-hand circular polarization. Polarization sense is determined looking in the direction in which the wave is traveling.
- Cross-polarized Antennas that are aligned with their polarization at right angles or accept opposite senses of circular polarization.

- Descending node The point on the ground track of the satellite orbit where the sub-satellite point (SSP) crosses the equator from the Northern Hemisphere into the Southern Hemisphere.
- Desense A problem characteristic of many radio receivers in which a strong RF signal overloads the receiver, reducing sensitivity.
- **Doppler effect** An apparent shift in frequency caused by a change in distance between transmitter and receiver.
- **Downlink** The frequency on which radio signals originate from a satellite for reception by stations on Earth.
- Earth station A radio station, on or near the surface of the Earth, designed to transmit or receive to/from a spacecraft.
- Eccentricity The orbital parameter used to describe the geometric shape of an elliptical orbit; eccentricity values vary from e = 0 to e = 1, where e = 0 describes a circle and e approaches 1 for a very long, thin ellipse.
- EIRP Effective isotropic radiated power. Same as ERP except the antenna reference is an isotropic radiator.
- Elevation Angle above the local horizontal plane, usually specified in degrees. (0° = plane tangent to the Earth's surface at your location; 90° = straight up, perpendicular to the plane of the Earth).
- EME Earth-Moon-Earth (see also Moonbounce)
- **Epoch** The reference time at which a particular set of parameters describing satellite motion (*Keplerian elements*) are defined.
- EQX The reference equator crossing of the ascending node of a satellite orbit, usually specified in UTC and degrees of longitude of the crossing.
- ERP Effective radiated power. System power output after transmission-line losses and antenna gain (referenced to a dipole) are considered.
- ESA European Space Agency. A consortium of European governmental groups pooling resources for space exploration and development.
- Faraday rotation A rotation of the polarization of radio waves when the waves travel through the ionosphere, in the presence of the Earth's magnetic field.
- FO-# The designator used for Japanese amateur satellites, by sequence number. Fuji-OSCAR 12 and Fuji-OSCAR 20 were the first two such spacecraft.
- *Geocenter* The center of the Earth.

- Geostationary orbit A satellite orbit at such an altitude (approximately 22,300 miles) over the equator that the satellite appears to be fixed above a given point.
- Ground gain Reflections from the ground in front of an antenna can add as much as 6 dB to the effective gain at certain elevation angles.
- Groundtrack The imaginary line traced on the surface of the Earth by the subsatellite point (SSP).
- Inclination The angle between the orbital plane of a satellite and the equatorial plane of the Earth.
- Increment The change in longitude of ascending node between two successive passes of a specified satellite, measured in degrees West per orbit.
- Iskra Soviet low-orbit satellites launched manually by cosmonauts aboard Salyut missions. Iskra means "spark" in Russian.
- JT65 A digital mode used for EME communications.
- Keplerian Elements The classical set of six orbital element numbers used to define and compute satellite orbital motions. The set is comprised of inclination, Right Ascension of Ascending Node (RAAN), eccentricity, argument of perigee, mean anomaly and mean motion, all specified at a particular epoch or reference year, day and time. Additionally, a decay rate or drag factor is usually included to refine the computation.
- *LEO* Low Earth Orbit satellite such as the Phase 1 and Phase 2 OSCARs.
- LHCP Left-hand circular polarization.
 Libration fading Rapid fading of EME signals caused by changing relative geometry of reflecting features on the Moon's surface and an observer on

Earth.

- LNA Low noise amplifier a preamplifier mounted as close to the antenna terminals as possible for satellite and EME communication.
- LOS Loss of signal The time when a satellite passes out of range and signals from it can no longer be heard. This usually occurs just after the satellite goes below the horizon.
- Mean anomaly (MA) An angle that increases uniformly with time, starting at perigee, used to indicate where a satellite is located along its orbit. MA is usually specified at the reference epoch time where the Keplerian elements are defined. For AO-10 the orbital time is divided into 256 parts, rather than degrees of a circle, and MA (sometimes

- called phase) is specified from 0 to 255. Perigee is therefore at MA = 0 with apogee at MA = 128.
- **Mean motion** The Keplerian element to indicate the complete number of orbits a satellite makes in a day.
- *Microsat* Collective name given to a series of small amateur satellites having store-and-forward capability (OSCARs 14-19, for example).
- Molniya Type of elliptical orbit, first used in the Russian Molniya series, that features a ground track that more or less repeats on a daily basis.
- Moonbounce A common name for EME communication in which signals are bounced off the Moon before being received.
- *NASA* National Aeronautics and Space Administration, the US space agency.
- Nodal period The amount of time between two successive ascending nodes of satellite orbit.
- Orbital elements See Keplerian Elements.
- Orbital plane An imaginary plane, extending throughout space, that contains the satellite orbit.
- OSCAR Orbiting Satellite Carrying Amateur Radio.
- **PACSAT** Packet radio satellite (see **Microsat** and **UoSAT-OSCAR**).
- Parabolic (dish) antenna An antenna reflector that is a portion of a paraboloid of revolution. Used mainly at UHF and higher frequencies to obtain high gain and narrow beamwidth when excited by one of a variety of driven elements placed at the dish focus to illuminate the reflector.
- **Pass** An orbit of a satellite.
- **Passband** The range of frequencies handled by a satellite translator or transponder.
- Path loss The total signal loss between transmitting and receiving stations relative to the total radiated signal energy.
- **Perigee** The point in a satellite's orbit where it is closest to Earth.
- Period The time required for a satellite to make one complete revolution about the Earth. See Anomalistic period and Nodal period.
- **Phase I** The term given to the earliest,

- short-lived, low Earth orbit (LEO) OSCAR satellites that were not equipped with solar cells. When their batteries were depleted, they ceased operating.
- Phase 2 LEO OSCAR satellites.
 Equipped with solar panels that powered the spacecraft systems and recharged their batteries, these satellites have been shown to be capable of lasting up to five years (OSCARs 6, 7 and 8, for example).
- Phase 3 Extended-range, highelliptical-orbit OSCAR satellites with very long-lived solar power systems (OSCARs 10 and 40, for example).
- **Phase 4** Proposed OSCAR satellites in geostationary orbits.
- Polar Orbit A low, circular orbit inclined so that it passes over the Earth's poles.
- Precession An effect that is characteristic of AO-10 and AO-40 orbits. The satellite apogee SSP will gradually change over time.
- Project OSCAR The California-based group, among the first to recognize the potential of space for Amateur Radio; responsible for OSCARs I through IV.
- QRP days Special orbits set aside for very low power uplink operating through the satellites.
- RAAN Right Ascension of Ascending Node. The Keplerian element specifying the angular distance, measured eastward along the celestial equator, between the vernal equinox and the hour circle of the ascending node of a spacecraft. This can be simplified to mean roughly the longitude of the ascending node.
- **Radio Sputnik** Russian Amateur Radio satellites (see **RS** #).
- **Reference orbit** The orbit of Phase II satellites beginning with the first ascending node during that UTC day.
- RHCP Right-hand circular polarization.
 RS # The designator used for most
 Russian Amateur Radio satellites (RS-1 through RS-15, for example).
- Satellite pass Segment of orbit during which the satellite "passes" nearby and in range of a particular ground station.
- Sidereal day The amount of time required for the Earth to rotate exactly 360° about its axis with respect to the "fixed" stars. The sidereal day contains 1436.07 minutes (see *Solar day*).

- Sidereal month The Earth and Moon complete their mutual orbit (with respect to fixed stars) every 27.3 days, one sidereal month.
- Solar day The solar day, by definition, contains exactly 24 hours (1440 minutes). During the solar day the Earth rotates slightly more than 360° about its axis with respect to "fixed" stars (see Sidereal day).
- Spin modulation Periodic amplitude fade-and-peak resulting from the rotation of a satellite's antennas about its spin axis, rotating the antenna peaks and nulls.
- SSP Subsatellite point. Point on the surface of the Earth directly between the satellite and the geocenter.
- System noise temperature Used in EME system evaluation, a measure of noise picked up by the antenna plus noise generated in the receiver.
- **Telemetry** Radio signals, originating at a satellite, that convey information on the performance or status of onboard subsystems. Also refers to the information itself.
- Transponder A device onboard a satellite that receives radio signals in one segment of the spectrum, amplifies them, translates (shifts) their frequency to another segment of the spectrum and retransmits them. Also called linear translator
- UoSAT-OSCAR (UO #) Amateur Radio satellites built under the coordination of radio amateurs and educators at the University of Surrey, England.
- Uplink The frequency at which signals are transmitted from ground stations to a satellite.
- Visibility Circle The range of area on the Earth that are "seen" by a satellite. This is also called the "footprint" for that satellite.
- Window Overlap region between acquisition circles of two ground stations referenced to a specific satellite.
 Communication between two stations is possible when the subsatellite point is within the window.
- WSJT-X A suite of computer software that includes tools for EME communication.

Digital Communications

In this operating supplement to the ARRL Handbook, updated in early 2018, Steve Ford, WB8IMY, discusses the techniques involved in assembling and configuring station components for operating on the various HF and VHF digital modes. Today's digital communication choices range from keyboard based modes like classic RTTY, packet radio and PSK31, to JT65, FT8, digital voice, local highspeed multimedia networks and VHF/UHF networks linked by the internet. Related information may be found in the Modulation and **Digital Protocols and Modes** chapters. Unless otherwise noted, references to other chapters refer to chapters in the print version of the ARRL Handbook's current edition.

Amateur digital communication has always been a niche activity, but it has grown substantially over the years. From the end of World War II until the early 1980s, radioteletype, better known as RTTY, was the Amateur Radio digital mode. If you had visited an amateur RTTY station prior to about 1977, you probably would have seen a mechanical teletype machine, complete with rolls of yellow paper. The teletype may have been connected to the transceiver through an interface known as a TU, or terminal unit. An oscilloscope would probably have graced the layout as well, used for proper tuning of the received signal.

When affordable microprocessor technology appeared in the late 1970s, terminal units evolved as well. Some included self-contained keyboards and video displays, making the mechanical teletype obsolete. As personal computers evolved, they became perfect companions for TUs. In this configuration, the PC functioned as a "dumb terminal," displaying the received data from the TU and sending data to the TU for transmission. TUs of this era offered ultra-sharp receive filters that allowed hams to copy weak signals amid interference.

In the late 1980s, conventional terminal units began to yield to sophisticated microprocessor devices known as multimode controllers. As the name suggests, these compact units handle several different digital modes in one package, typically RTTY, packet, AMTOR and PACTOR. Like TUs, multimode controllers are stand-alone devices that communicate with a personal computer acting as a dumb terminal. All the heavy lifting is being done by the controller and its self-contained software known as firmware.

In the early 1990s, sound cards appeared for personal computers. As sound cards became more powerful, hams began to realize their potential. With the right software, a sound card could take received audio directly from the radio and translate it into digital information. The same sound card could also create various forms of digital audio modulation for transmission. The first "sound card mode" was PSK31, developed by Peter Martinez, G3PLX. In the years that followed, sound cards became more powerful and versatile. Hams responded by developing new digital modes to take advantage of the advances.

Hardware controllers are still with us, but they are primarily used for modes like packet and PACTOR that require more processing muscle and precision timing than a typical personal computer can provide on its own. Other amateur digital modes such as D-STAR depend on specially designed transceivers that combine the radio hardware with dedicated digital processing firmware.

1 Sound Device Modes

Sound device technology dominates the amateur HF digital communications world. Although the term *sound card* is commonly used, the techniques discussed in this section apply to motherboard-embedded sound chip sets, which are extremely common in computer systems today, and to external sound processing devices. We'll use the term "sound device" to refer to any of these hardware implementations.

The sound device modes in use today include PSK, RTTY, MFSK16, Olivia, JT65, FT8, Hellschreiber, the WSJT EME and meteor-scatter modes, WSPR, and many more. There are also sound-device applications for digital voice, discussed later in this article and for slowscan TV, discussed in the **Image Communications** supplement.

As this was written in early 2018, FT8 had become the most popular HF digital communication mode. However, like JT65 and other modes in the WSJT-X software suite developed by Joe Taylor, K1JT, FT8 is limited to exchanges of signal reports and grid square designators. For actual conversations, the 31-baud version of PSK, known as PSK31, is still dominant. The popularity of these modes notwithstanding, radioteletype (RTTY) remains the chief HF mode for contesting and DXing, although it is possible that FT8 could make serious inroads in these applications as well.

All other HF digital modes play minor roles, but each has characteristics that provide benefits depending on the use case. Olivia and MFSK16, for example, provide more robust copy under poor conditions. WSPR is the most popular mode for propagation test-

ing. On VHF and above, the WSJT-X software suite offers modes specifically designed for meteor scatter and moonbounce work. WSJT-X is free and available for Windows, Linux, and macOS at physics.princeton.edu/pulsar/k1jt/wsjtx.html.

Regardless of the mode in question, the sound device functions as the critical link. It is put to work as a digital-to-analog (D/A) and analog-to-digital (A/D) converter. In its A/D role, the sound device takes receiver audio and converts it to digital information. During transmission, the sound device is used

as a D/A converter, taking digital information from the software application and creating a corresponding analog signal that is fed to the transceiver. (For more information on A/D and D/A converters, see the **DSP and SDR Fundamentals** chapter of this *Handbook*.)

1.1 The Evolution of Sound Devices

In the early days of Amateur Radio sound device modes, the computer sound card (or motherboard sound chipset) was *the* critical

component in every amateur station. There was an obsession, at least in some circles, in having the highest-quality sound device possible. The idea was that a high-end device would minimize noise and distortion, thereby making it possible to copy even the weakest digital signals.

There is some truth to the notion that a pricey sound device can make a difference, but as it turns out, the difference is rather small – certainly not enough to justify the cost. The exceptions may be activities such as moonbounce in which the signals are often extraordinarily weak.

But for most amateur applications today, the sound device has moved out of the computer and into external interfaces, or even into transceivers themselves. See Figure 1. Rather than traditional interfaces that merely passed analog audio signals between radios and computers, modern interfaces contain their own A/D and D/A devices. The connection to the computer is strictly for the transfer of digital information, typically through a USB cable.

Transceivers are increasingly taking the next step by bringing the A/D and D/A conversion process into the radio. There is no external interface whatsoever; the radio connects directly to the computer. We can expect to see an increasingly number of transceivers taking this approach.

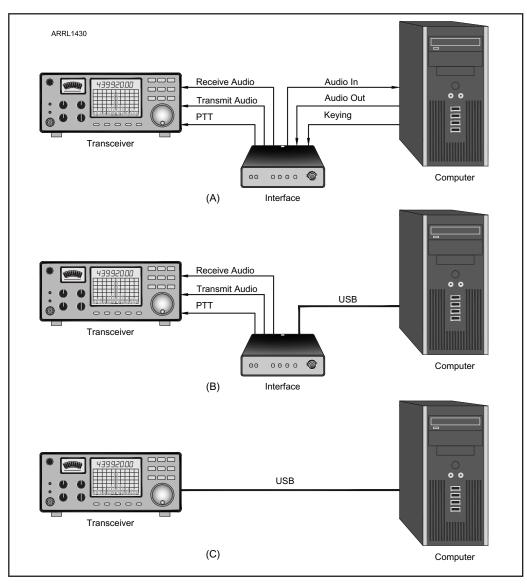

Figure 1 — Three of the most common configurations for interfacing your transceiver with your computer. (A) The most common setup for many years was based on an interface that took transmit and receive audio from the computer sound card, along with transmit/receive keying from one of the computer's COM ports, and passed everything to the transceiver in a way that kept the signal lines isolated. This type of interface is increasingly uncommon. (B) Many interfaces available at the time this book was written are USB devices. A single USB cable plugs into the computer. Not only is the computer sound card not used, the interface contains its own sound device. In turn, the interface supplies transmit audio to the radio, processes receive audio from the radio and handles transmit/receive keying. (C) The future will likely see the disappearance of the interface entirely as transceivers incorporate their own computer interfacing. Today, several moderate to higher-priced rigs have added this feature.

AFSK AND FSK

Most sound device modes rely on some form of frequency and/or phase-shift keying to create digitally modulated RF signals. This modulation takes place at audio frequencies with the sound device audio output applied directly to an SSB voice transceiver, either at the microphone jack or at a rear-panel accessory jack, and is called audio frequency shift keying (AFSK).

RTTY, PACTOR I and AMTOR signals can be sent using AFSK, and often are. It is

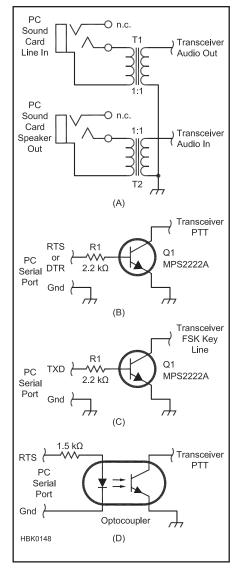

Figure 2 — Some commonly used interface circuits. At A, isolating the sound device and transceiver audio lines. T1 and T2 are 1:1 audio isolation transformers. At B. a. simple circuit to use the computer COM port to key your transceiver PTT, and at C, a similar circuit for FSK keying. Q1 is a general purpose NPN transistor (MPS2222A, 2N3904 or equivalent). At D, an optocoupler can be used to provide more isolation between radio and computer. On a DB9 serial port connector: RTS, pin 7; DTR, pin 4; TxD, pin 3; GND, pin 5.

also possible to transmit these modes by applying discrete binary data directly to the transceiver. This technique is known simply as direct frequency-shift keying (FSK).

For example, each character in the Baudot RTTY code is composed of five bits. When modulated with AFSK, a "1" bit is usually represented by a 2125-Hz tone and is known as a mark. A "0" bit is represented by a 2295-Hz tone called a space. The difference between the mark and space is 170 Hz, called the *shift*. When applied to a single-sideband transceiver, this AFSK audio signal effectively generates an RF output signal that shifts back and forth between the mark and space frequencies.

A transceiver that supports FSK, however, can accept mark/space digital data directly from the computer and will use that information to automatically generate the frequencyshifting RF output. No audio signal is applied to the transceiver when operating FSK.

Is there an advantage to using AFSK or FSK? In years past, transceivers that did not support FSK operation often did not allow the use of narrow IF filtering. Those filters were reserved for CW, not the SSB voice mode used with AFSK. If you wanted to use RTTY with such a rig, you had to use AFSK and contend with the wider (2.4 kHz or so) SSB IF bandwidth, or else add an external audio filter. FSK-capable transceivers, on the other hand, allowed the RTTY operator to select narrow CW filters, reducing receive interference in crowded bands.

Many of today's transceivers offer adjustable-bandwidth digital signal processing (DSP) filters in the IF stages that can be used with any operating mode. This has effectively eliminated the FSK advantage, at least for receiving.

The appeal of FSK remains, however, when it comes to transmitting. A properly modulated AFSK signal is indistinguishable from FSK, but it is relatively easy to overdrive an SSB transmitter when applying an audio signal from a sound device (more on this in the next section). With FSK this is never an issue. You simply feed data from the computer to the radio; the radio does the rest.

This is why many RTTY operators still use FSK, and it's why transceiver manufacturers

still offer FSK modes (sometimes labeled DATA or RTTY) in their products. Several sound device interfaces support FSK by providing a dedicated TTL circuit between the computer COM port, where the FSK data appears, and the transceiver FSK input. When used in this fashion, the sound device does not generate a transmit audio signal at its output. Instead, the RTTY software keys the various lines at the COM port to send the FSK data.

If the interface you've chosen doesn't support FSK, you can build your own TTL interface using the circuit shown in Figure 2. This simple circuit uses a transistor that is keyed on and off by data pulses appearing on the COM port TxD pin (pin 3 on a 9-pin COM port).

It is important to note that FSK transceiver inputs can only be used for modes that are based on binary FSK, typically with 170 or 200-Hz shifts. These modes include RTTY, PACTOR I and AMTOR. You cannot use the FSK input to transmit multi-frequency or phase-shift modulated signals such as MFSK16 or PSK

1.3 Transmit Audio Levels

When applying digitally-modulated audio to a transceiver, it is critical to maintain proper levels. By overdriving the transceiver's audio input, you may create a wide, distorted RF signal that will be difficult, if not impossible, to decode at the receiving end. Such an overmodulated signal will also cause considerable interference on adjacent frequencies.

As you increase the transmit audio output from your sound device, pay careful attention to the ALC indicator on your transceiver. The ALC is the automatic level control that governs the audio drive level. When you see your ALC display indicating that audio limiting is taking place, or if the display indicates that you are exceeding the ALC "range," you are feeding too much audio to the trans-

Monitoring the ALC by itself is not always effective. Many radios can be driven to full output without budging the ALC meter out of its "nominal" range. Some radios become decidedly nonlinear when asked to provide SSB output beyond a certain level (sometimes

> this nonlinearity can begin at the 50% output level). We can ignore the linearity issue to a certain extent with an SSB voice signal, but not with digital modes because the immediate result, once again, is splatter.

> simplest method to tell if your signal is clean is to ask someone to give you an

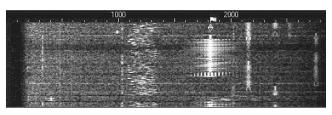

Figure 3 — The waterfall spectrum display built into popular sound device software can help detect overdriven PSK31 signals. Note the lines extending from the signal on the right, near the 2000 Hz marker, indicating splatter. The other signals are from properly adjusted transmitters.

evaluation on the air. For example, PSK31 programs commonly use a waterfall audio that can easily detect "dirty" signals. The splatter appears as rows of lines extending to the right and left of your primary signal, as shown in **Figure 3**. (Overdriven PSK31 signals may also have a harsh, clicking sound.)

If you are told that you are splattering, ask the other station to observe your signal as you slowly decrease the audio level from the sound device or processor. When you reach the point where the splatter disappears, you're all set.

Don't worry if you discover that you can only generate a clean signal at, say, 50 W output. With PSK31 and most other sound device modes, the performance differential between 50 W and 100 W is inconsequential.

1.4 Sound Device Software

As you can see in **Table 1**, there is great deal of software available for sound-device-based digital modes. Some of the software applications are free, while others require registration and a fee.

There are applications dedicated to modes, such as *DigiPan* (PSK31) and *MMTTY* (RTTY). The trend in recent years has been to multimode programs that support many different digital modes in a single application.

Most software applications rely on *panoramic reception* where the software processes and displays all signals detected within the bandwidth of the received audio signal. The signal "signatures" are often shown within continuously scrolling *waterfall* displays such as the one shown in **Figure 4**.

Panoramic reception is particularly popular among PSK31 operators because the narrow signals tend to cluster within a relatively small range of frequencies. By using panoramic reception, an operator can simply click the mouse cursor on one signal trace in the waterfall after another, decoding each one in turn.

The weakness of panoramic reception appears when wide IF filtering is used to display as many signals as possible. The automatic gain control (AGC) circuit in the receiver is acting on everything within that bandwidth, working hard to raise or lower the overall gain according to the overall signal strength. That's fine if all the signals are approximately the same strength, but if a very strong signal appears within the bandwidth, the AGC will *reduce* the gain to compensate. The result will be that many of the signals in the waterfall display will suddenly vanish, or become very weak, as the AGC drops the receiver gain. In cases where an extremely strong signal appears, all signals except the rock crusher may disappear completely.

The alternative is to use narrower IF or audio filter settings. These will greatly reduce the waterfall display width, but they will also remove or reduce strong nearby signals.

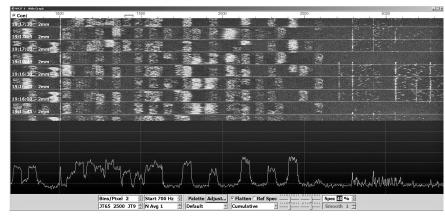

Figure 4 — Many FT8 signals are visible in this view of a WSJT-X panoramic waterfall display.

2 Packet Radio

Although the heyday of traditional packet radio has passed, it still survives in the form of networks devoted to specific applications such as emergency communication. A variant of packet radio also finds popular use in the Automatic Packet Reporting System (APRS), addressed in a later section.

2.1 The Packet TNC

In the beginning, there was X.25, a protocol for wide-area digital networks that typically communicated over telephone lines. X.25 works by chopping data into strictly defined packets or frames of information. Each packet is sent to the destination device where it is checked for errors. If errors are discovered, the packet must be sent again to ensure that received data is 100% error free.

In the early 1980s, amateurs began adapting X.25 for over-the-air digital communications. The result was AX.25. The new AX.25 protocol worked in much the same way, although it identified each message by sender and destination station call signs and added a Secondary Station ID (SSID) in a range from 0 through 15.

To create and decode these AX.25 packets, hams invented the terminal node controller, or TNC. TNCs do much more than assemble and disassemble data; they are miniature computers unto themselves. A TNC is also programmed to work within a radio network where there may be other competing signals. For example, to maximize the throughput for everyone on the same frequency, a TNC is designed to detect the presence of other data signals. If it has a packet to send, but detects a signal on the frequency, it will wait until the frequency is clear. TNCs also have a variety of user adjustments and other features, such as a mailbox function to store messages when the operator is away.

Regardless of the changes in packet radio, the TNC is still a vital component. In essence, a TNC functions as a "radio modem." It acts the middleman between your radio and your computer. The TNC takes data from your computer, creates AX.25 packets and then transforms the AX.25 formatted data into audio signals for transmission by the radio. Working in reverse, the TNC demodulates the received audio, changes it back into data. disassembles the AX.25 packets and sends the result to the computer.

For 300 and 1200-baud applications, TNCs create signals for transmission using AFSK. The most common is 1200 baud packet, used primarily at VHF. When creating a 1200-baud signal, a mark or 1 bit is represented by a frequency of 1200 Hz. A space or 0 bit is represented by a frequency of 2200 Hz. The transition between each successive mark or

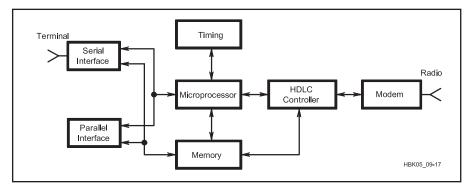

Figure 5— A block diagram of a typical packet radio TNC.

space waveform happens at a rate of 1200 baud. The frequencies of 1200 and 2200 Hz fit within the standard narrowband FM audio passband used for voice, so that AFSK is accomplished by simply generating 1200 and 2200 Hz tones and feeding them into the microphone input of a standard FM voice transmitter.

FSK, not AFSK, is used for 9600 baud packet. The data signal is filtered and encoded and then applied directly to the FM transmitter, after the microphone amplifier stage, through a dedicated port.

A block diagram of a typical TNC is shown in **Figure 5**. You'll note that it has a serial interface connecting to a "terminal." Most commonly, the terminal is a full-fledged computer running terminal software. Data flows to the computer and vice versa via this interface. At the heart of the TNC is the microprocessor and the attendant High-level Data Link Controller, or HDLC. The microprocessor is the brain of the unit, but the HDLC is responsible for assembling and disassembling the packets. The modem is simply that — a modulator (changing data to audio tones) and demodulator (changing audio tones back to

You can still find TNCs for sale from several manufacturers. There are also several transceivers with packet TNCs built in.

Another solution is a software TNC known as the AGW Packet Engine, or AGWPE, developed by George Rossopoylos, SV2AGW. The software is downloadable at www.sv2agw. com/downloads. With AGWPE and a sound device interface as described in this article, it is possible to operate packet radio without a hardware TNC — if your primary packet software application includes the ability to interface with AGWPE.

2.2 TNCs and Radios

Tones for 1200 baud can be fed directly into the microphone input of any VHF FM voice transceiver with an appropriate cable.

Packet at 9600 baud requires an FM transceiver with a dedicated 9600-baud packet input, as noted earlier.

If you opt to craft your own cable, check your transceiver manual for the wiring diagram of the microphone jack. In most cases, there are separate connections for the audio input and the push-to-talk (PTT) line. (The TNC grounds the PTT line to key your transceiver.) Some transceivers also make receive audio available at the microphone jack for use with speaker/microphone combos. You can use this line to feed audio to the TNC. If it isn't available, you will have to make a separate connection to the transceiver's external speaker jack.

When you are setting up your TNC, be careful about the transmit audio level. Too high a level will create distorted signals that won't be decodable at the receiving station.

An easy way to check your transmitted signal is to use the TNC calibrate function. Get to the command mode (CONTROL-C) and enter cmd: CALIBRATE. Listen to your transmitted signal with another rig and raise the audio level from the TNC until the received volume seems to stop increasing. Now reduce the audio from the TNC until you can just hear a volume decrease in the receiver. Reduce it a bit more and you're done. Exit the calibrate function.

Some TNCs have an audio output adjustment on the board, some have an adjustment accessible through a hole in the side of the unit, and some have two fixed output levels selectable with a jumper. If one of these does not work, you may have to open the transceiver and find the mic gain control. If this is necessary, be sure you adjust the mic gain control and not the deviation control (which can change the bandwidth of your signal).

2.4 TNC Timing

The TNC's TXDELAY parameter specifies the delay interval between the time the TNC keys the radio and the time it starts sending data. Normally 300-400 ms are adequate, but some transceivers take longer to settle after the keying line is triggered. If you have a problem being heard and your audio seems normal, try increasing TXDELAY to 400-600 ms

On a busy network, packets and packet acknowledgements fly back and forth at a furious rate. One way to keep interference to a minimum is to manipulate the RESP and DWAIT parameters in conjunction with PERSIST and SLOTTIME to allow staggered transmissions.

RESP is the time delay between reception of a packet and transmission of an acknowledgement. DWAIT sets the delay between the time when activity is last heard on the channel and the moment your radio transmits. You should set values of RESP and DWAIT to the values recommended in your area (check with the person managing the local network or PBBS). Your TNC probably accepts a value in "counts" rather than in milliseconds, so don't forget to convert by the proper value to arrive at the correct timing value in milliseconds. For example, if you have been asked to set DWAIT to 600 ms and the units of DWAIT for your TNC are 10 ms per count, then you would command DWAIT = 60.

Most TNCs contain commands called PERSIST and SLOTTIME, which help enormously in avoiding interference. PERSIST sets the probability that a packet will be transmitted during a given time interval called a SLOTTIME. The parameter SLOTTIME governs the interval between transmission timing "slots." Initially, PERSIST should be set to approximately 64 and SLOTTIME to a value of about 10, which is equivalent to 100 ms.

FRACK (frame acknowledgement) should be set to 6 and RETRY to 10. FRACK sets the number of seconds between retries and RETRY sets the number of times your TNC will try to send a packet and gain acknowledgement of it before it gives up and disconnects

2.5 Monitoring

Start by listening to an active packet frequency in your area. With the radio cable connected, turn on your radio and increase the receiver volume partway. Some TNCs include an LED indicator that shows that the TNC is receiving audio. Turn up the squelch control on the radio until the LED is extinguished. Tune the rig to any odd numbered frequency between 144.91 and 145.09, or between 145.61 and 145.79 MHz, and set the rig for simplex operation. Your best bet may be to search for a DX PacketCluster, or try monitoring APRS activity on 144.39 MHz. When you hear the buzzing packet signals and see text on your screen, you'll know you've hit the jackpot.

Depending on the type of activity you are monitoring, you may see what appears to be nonsense. If you are monitoring APRS, you'll see strings of numbers. These are latitude/longitude position reports. On PacketClusters, you'll see DX call signs and frequencies.

2.6 "Connected" vs "Unconnected"

When discussing TNCs and networks, it is important to understand the difference between connected and unconnected communication.

If you are simply monitoring local packet transmissions, your TNC is in an *unconnected* state. What you see is what you get. If a signal is garbled by noise or interference, you'll see nothing on your screen (unless you've enabled the PASSALL function, in which case you'll see gibberish). If you transmit an unconnected packet, the signal simply leaves your antenna destined for nowhere in par-

ticular. Some stations may decode it, some may not.

When your TNC is operating in a *connected* state, everything changes. When you are connected, your station is linked to another station in a "virtual" sense. In a connected state, every packet you send is intended specifically for the receiving station (even though others can see it).

When your TNC transmits a packet, it starts a countdown clock. If the clock reaches zero before your TNC receives an acknowledgement (known as an *ACK*) that the packet arrived without errors, it will send the same packet again. When the packet is finally acknowledged, the TNC will send the next packet. And so it goes, one packet after another. The operator at the other station may also be sending packets to you since this communication process can flow in both directions simultaneously.

The big advantage of the connected state is that data is delivered error-free. One packet station can connect to another directly, or through a series of relaying stations. Error-free can be a disadvantage, too. Specifically, a connected state works best when signals are strong and interference is minimal.

Remember that if too many packets are lost — by either not arriving at all or arriving with errors — the link will fail. That's why AX.25 packet radio tends not to work well on the HF bands. With all the noise, fading and interference, packets are often obliterated in route.

Unconnected packets are ideal for applications where you are transmitting essentially the same information over and over. Since unconnected packets can be decoded by any station, they are an excellent means of disseminating noncritical data (data that doesn't need guaranteed error-free delivery) throughout a given area. If a station fails to decode one packet, it merely waits for the next one. APRS uses exactly this approach.

3 The Automatic Packet Reporting System (APRS)

The Automatic Packet/Position Reporting System, better known as *APRS* (**aprs.org**), is the brainchild of Bob Bruninga, WB4APR. In fact, APRS is a trademark registered by WB4APR. The original concept behind APRS involved tracking moving objects, and that's still its primary use today. However, APRS has been evolving to become an amateur network for other applications such as short text messaging, either from ham to ham, or between hams and non-hams through APRS internet gateways.

Mobile APRS stations communicate their positions based on data provided by on-board Global Positioning System (GPS) receivers. The GPS receivers are attached to either packet radio TNCs or simplified packet devices known as *position encoders*, which in turn are connected to transceivers (see **Figure 6**). At receiving stations, various APRS software packages decode the position information and display the results as icons on computer-generated maps such as the one shown in **Figure 7**. When a station moves and transmits a new position, the icon moves as well.

Virtually all APRS activity takes place today on 144.39 MHz using 1200-baud packet TNCs and ordinary FM voice transceivers. In areas where the APRS network is particularly active, you may hear traffic on 445.925 MHz as well. There is also some activity on HF.

3.1 Setting Up an APRS Station

If you own a 2-meter FM voice transceiver, you already have the primary component of your APRS station. Tune your radio to 144.39 MHz and listen for packet transmissions. If

Figure 6 — A 2-meter FM handheld transceiver attached to an APRS position encoder.

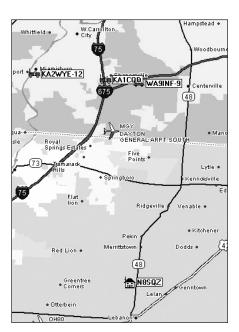

Figure 7 — A snapshot of APRS activity using UI-View software. Note the icons representing various mobile and fixed stations

you hear them, it means you have APRS activity in your area. To decode APRS packets, you'll need a TNC, or a transceiver that has

There are several packet-ready transceivers that also have built-in GPS receivers. However, if all you want to do is monitor APRS activity, you do not need a GPS receiver. If you want to participate in the local APRS network from a fixed (non-moving) station such as your home, you still do not

need a GPS receiver. Just determine your home latitude/longitude coordinates and you can use them to establish the location of your home station on the network. There are numerous sites on the internet that will convert your home address to a correct latitude and longitude.

The final component of your APRS station is software. You'll need software to display the positions of APRS stations, along with other information contained in their transmissions. APRS software is also essential if you want to communicate over the APRS network from a fixed or portable station. Note, however, that APRS software is not necessary for mobile stations that wish to merely transmit APRS beacons for tracking purposes. That function is carried out automatically using the GPS receiver and APRS-compatible TNC or tracking device; it does not depend on soft-

The most popular APRS Windows program is UI-View. UI-View was created by the late Roger Barker, G4IDE. You'll find it online at www.ui-view.net/. The 16-bit version is free for downloading. To use the 32-bit registered version, hams are asked to donate to their local cancer charities. Details are available on the UI-View website. Another worthwhile program for Windows is PinPoint APRS, which you will find at www.pinpointaprs.com. For the Macintosh, there is MacAPRS available from www.winaprs. **com**. For Linux there is *Xastir*, available for download at sourceforge.net/projects/ xastir/.

APRS software, regardless of the operating system, is designed to talk to the packet TNC, processing the incoming APRS data and creating icons on your computer screen. The application also uses the TNC to transmit APRS data. This means that the software and the TNC must communicate with each other at the same baud rate. Every APRS application has a setup menu to program the correct parameters for various TNCs.

Depending on the software, there may be other features such as logging or messaging. APRS software changes rapidly, so check the help file or manual for specific instructions.

3.2 Maps and APRS

No matter which APRS software you choose, one critical aspect is the mapping function itself. To get the most from APRS, your software maps must be as comprehensive as possible, preferably with the ability to show detail down to street level.

Downloadable APRS software applications generally do not come with detailed maps. Detailed map files are numerous and large, impractical to bundle with every APRS program. Instead, most applications are designed to import user-created custom maps, or to work with existing commercial mapping programs such as Microsoft Streets, Delorme Street Atlas and Precision Mapping.

UI-View, for example, can automatically load and display maps from Precision Mapping. You must purchase and install Precision Mapping on your PC, then download and install a small Precision Mapping "server" application into *UI-View*.

Each APRS transmission includes characters that define the type of map icon that will be displayed at the receiving end. If you are operating a fixed station, your APRS software will allow you to choose your icon. If you are a mobile station using a traditional TNC, you'll need to define your chosen icon in your beacon statement. APRS-compatible TNCs give you the ability to do this. APRS position encoders also allow you to choose your icon when you program the unit. Your mobile icon might be a car, boat or airplane.

3.3 APRS Position Encoders

If you aren't blessed with a transceiver that offers a built-in TNC and GPS receiver, you can create a mobile APRS station with any VHF FM transceiver, a TNC and a GPS receiver. Wire everything together, connect an antenna and dc power and you're set. For hams on the go, however, it's common to replace the full-fledged TNC with an APRS position encoder, also referred to as an APRS tracker. A position encoder is a compact device designed for one purpose: to receive data from the GPS receiver, assemble APRS packets from the data and create modulated signals for use by the transmitter. Some position encoders include GPS receivers in their designs. You'll even find position encoders that are complete packages incorporating tiny GPS receivers and low power FM transmitters.

To use a position encoder, you must program it the same way that you initially program a TNC. Like TNCs, position encoders connect to computer serial or USB ports for programming and most come with their own programming software. You must enter your call sign and other information such as your beacon interval (how often you want the position encoder to transmit your position). Most position encoders allow you to set the beacon interval to a certain amount of time (say, every two minutes). Some position encoders can be configured to transmit position beacons after a certain distance (every mile), or whenever the vehicle turns a corner.

3.4 APRS Networking Tips

One of the key features of APRS is that while it uses AX.25 to transport its messages, it essentially ignores all the AX.25 connection-oriented baggage. Unlike traditional packet radio, APRS stations do not establish "connections" with each other. Instead, APRS packets are sent to no one in particular, meaning to *everyone*.

Every APRS station can function as a digital repeater, or *digipeater*. So, if it receives a packet, it will retransmit the packet to others. As other digipeaters decode the same packet, they will also retransmit and spread it further. This is known as *flooding* and is illustrated in **Figure 8**.

As an APRS user, you can set up your station to address its packets through specific digipeaters according to their call signs. But when you're traveling, how do you determine which digipeaters you should use?

PATHS AND ALIASES

In the packet world, nodes and digipeaters can have *aliases*. A digipeater call sign may be W1AW-1, but it can also carry an alias, using the MYALIAS command in the digipeater TNC. Perhaps the digipeater alias would be NEWNG (meaning the ARRL HQ home town of Newington). You can route packets through the digipeater by addressing them to W1AW-1, or simply by addressing them to NEWNG. Any station that is set up to respond to an alias can handle your packets automatically, even if you don't know its call sign.

Unlike typical packet use of aliases in which a given single station has a specific alias, APRS specifies standard digipeater aliases that nearly all stations use. This means that you can travel anywhere in the country and still participate in the APRS network without knowing digipeater call signs. (Otherwise, you'd have to reconfigure your TNC whenever you moved from one area to another.)

The most common APRS digipeater alias is *WIDEn-N*. The letters "n" and "N" represent numbers. The first (left-most) "n" designates how many WIDE digipeaters will relay your packets, assuming they can receive them. WIDE2, for instance, is the same as saying that you want your packets relayed through *two* WIDE digipeaters. The second

"N" is the *Secondary Station Identifier* (SSID). The SSID is used in APRS networks as a means of limiting how often (and how far) a packet can be repeated.

Here's how it works. Each time your packet traverses a WIDEn-N digipeater, the digipeater subtracts 1 from the SSID as it retransmits. The next digipeater deducts 1 and so on until the SSID reaches zero, at which time the packet will not be repeated. This has the effect of limiting the flood radius. See **Figure 9**.

When you configure a TNC or position encoder for use with APRS, you can use these aliases to set up the paths for the beacon packets you'll be transmitting. In most devices this is accomplished with the UNPROTO parameter, sometimes simply referred to as the "Path." If you are a fixed station (a station at home, for instance), set your path as WIDE2-2 (or with a traditional TNC UNPROTO statement, set it to APRS VIA WIDE2-2). This designates that your reports will be relayed by *two* WIDEn-N digipeaters and limits the spread beyond those repeaters to just two retransmissions. Set your TNC to beacon once every 30 minutes. That's sufficient for a fixed station.

If you are running APRS from a car, try WIDE1-1,WIDE2-1 (or APRS VIA WIDE1-1,WIDE2-1). WIDE1-1 ensures that your packet will be picked up by at least one local digipeater or a home station acting as a fill-in digipeater and relayed at least once. WIDE2-1 gets your packet to another, presumably wider-coverage digipeater, but limits the retransmissions beyond this point. It's waste-

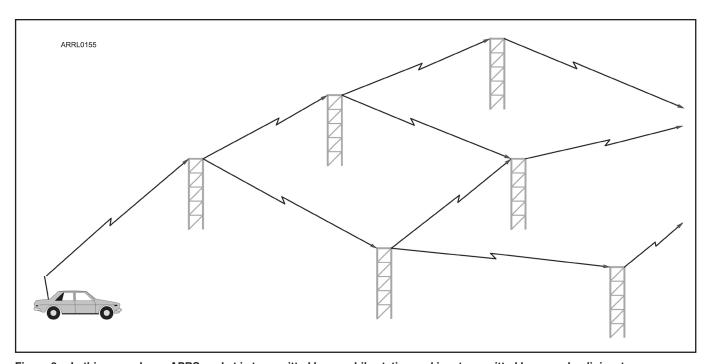

Figure 8 —In this example, an APRS packet is transmitted by a mobile station and is retransmitted by a nearby digipeater. Depending on how the mobile operator configured his TNC or tracker's path, the packet will be picked up and repeated by several other digipeaters. This is known as flooding.

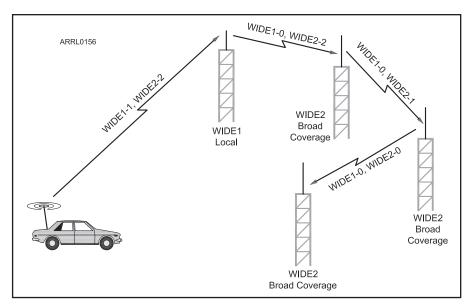

Figure 9 — By using the WIDEn-N system, we can limit packet flooding in a local network and greatly reduce congestion. The mobile station in this example has his path set as WIDE1-1, WIDE2-2. Notice how his packet propagates through the network and how the SSID number is reduced by one each time the packet is repeated through a digipeater with a corresponding alias. When it reaches the third WIDE2 digipeater, the counters all reach zero and digipeating stops.

ful of the network to set up wide coverage for a station that is rapidly changing its position anyway. Mobile stations that are in motion should also limit their beacon rate to once every 60 seconds, or once per mile, whichever comes first.

Never invoke extremely wide coverage, such as a WIDE5-5 path, unless you are way out in the hinterlands and need every relaying station available to get your packets into the network.

Another popular alias is the "single state" -SSn-N — to limit the spread of your packets to a specific state or area within a state. To keep packets within the state of Connecticut, for example, you could use the SSn-N alias in a path statement, like this: CT1-1, CT2-2. This path assures that local Connecticut stations (CT1-1) will repeat the packets, and that broad-coverage stations (CT2-2) will relay them throughout a large portion of the state. APRS digipeaters outside Connecticut, however, will not respond to these packets because they won't recognize the CT2-2 alias (although they will recognize an alias for their state). The packets will still be heard across state borders but will not be digipeated or add to the packet activity in a neighboring state.

4 PACTOR

PACTOR is a type of HF digital communication that, unlike many other HF modes, offers error-free text and file transfers. PACTOR communication resembles packet radio in that it establishes a "link" between two stations. Data is sent in discrete frames and each frame is acknowledged by the receiving station. This rapid back-and-forth exchange creates PACTOR's distinctive chirp-chirp signal. Through robust coding and sophisticated modulation techniques. PACTOR is often able to maintain the link even in the face of significant noise, fading and interference.

PACTOR I, introduced in the early 1990s, has been largely superseded by PACTOR II and III, which provide faster throughput in difficult conditions. Both PACTOR I and II generate signals that occupy 500-Hz bandwidths. PACTOR III offers even more efficient communication, but its signal occupies a bandwidth in excess of 2000 Hz.

The most recent version of PACTOR is PACTOR IV, which offers much greater throughput even when compared to PACTOR III. However, at the time this was written, FCC rules did not permit signaling rates greater than 300 baud below 28 MHz and PACTOR IV exceeds this limit. The ARRL has petitioned the FCC to change the rules to permit the use of higher signaling rates below

28 MHz, but at the time of this writing, the FCC had yet to act.

To set up a PACTOR station, you must purchase a stand-alone multimode controller that includes the PACTOR mode. Controllers manufactured by Kantronics (www.kantronics.com) and Timewave (www.timewave. com) include PACTOR I. For PACTOR II or III. vou must purchase a controller made by Special Communications Systems (www.scs**ptc.com**), the original developers of PACTOR.

Figure 10 illustrates a typical PACTOR station built around a multimode controller. The computer is functioning only as a dumb terminal for the controller in this application, so it does not have to be particularly powerful. All that is required is basic terminal software as described in the section on packet TNCs. More sophisticated software applications can provide a smoother, easy-to-use interface, but these require more capable computers.

A PACTOR station requires an SSB transceiver capable of switching from transmit to receive within approximately 30 ms. Most modern HF transceivers can meet this requirement, but not all. OST magazine Product Reviews test this specification for all HF transceivers. The transmit audio supplied by the controller can be fed to the microphone or accessory jack to operate AFSK, which is the standard procedure, although PACTOR I can also operate using FSK.

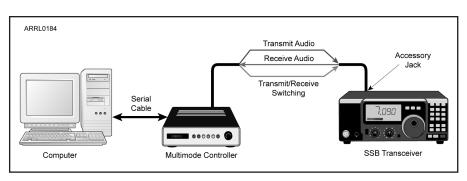

Figure 10 — A PACTOR station with a multimode controller. For PACTOR II and III operation, the controller must be a model manufactured by the SCS Corporation.

5 High Speed Multimedia (HSMM)

Wireless networking using IEEE 802.11 standards has seen explosive growth during the last several years. Coffee shops, fast-food restaurants, hotels, airports and many other high-traffic locations now include wireless internet (WiFi) hotspots. Some hotspots offer free internet access while other charge an access fee, payable with your credit card.

Wireless networks are also popular at home. Establishing a home network is as simple as installing a wireless router to manage the data flow from the broadband internet connection. The router allows one or more traditional desktop computers to tap the broadband connection through wired (usually Ethernet) access while simultaneously making the internet available wirelessly to one or more laptops.

All these home networking devices — routers, wireless access cards, and so on - are unlicensed FCC Part 15-regulated transceivers with RF outputs measured in milliwatts. A number of their channel frequencies overlap two Amateur Radio bands: 2.4 and 5.8 GHz. This means that hams can put them to work as "transceivers" under our Part 97 rules. See **Table 2** for specific frequencies.

By using consumer-grade routers, low-loss coaxial cable and gain antennas, hams can quickly establish high-speed, long-distance wireless networks on these 2.4 or 5.8 GHz frequencies. This type of operating is referred to as high speed multimedia, or HSMM.

With HSMM amateurs can operate several different modes at the same time, and usually do. HSMM is generally IP-based, and given enough bandwidth, radio amateurs have the capability to do the same things with HSMM that are done on the internet.

• Audio: This is technically digital voice, since it is two-way voice over an IP (VoIP) network similar to EchoLink and IRLP networks used to link many Amateur Radio

Table 2 **Wireless Network Frequencies in Amateur Bands**

Channel	Center Frequency
1	2.412 GHz
2	2.417 GHz
3	2.422 GHz
4	2.427 GHz
5	2.432 GHz
6	2.437 GHz
Channel	Center Frequency
132	5.660 GHz
136	5.680 GHz
140	5.700 GHz
149	5.745 GHz
153	5.765 GHz
157	5.785 GHz
161	5.805 GHz
165	5.825 GHz

repeaters over the internet. (VoIP is covered in a later section.)

- Video: Motion and color video modes, are called amateur digital video (ADV). This is to distinguish it from digital amateur television (DATV). DATV uses hardware digital coder-decoders (CODEC) to achieve relatively high-definition video like entertainment quality TV. The usual practice in HSMM radio is to use a far less expensive (often free) PC-based software video codec to achieve video communications quality signals in much smaller bandwidths.
- Text: Text exchanges via a keyboard are often used in HSMM radio, but they are similarly called by their internet or packet radio name: Chat mode, and if a server is available on the network, e-mail can also be
- Image: Image file transfers using file transfer protocol (FTP) can also be done, just as on the internet.
- Motion video: FTP of MPEG files can provide one-way video streaming of short
- Remote control: Individual devices or even complete stations can be remotely con-

• Mesh networking: A mesh is a wireless cooperative communication infrastructure in which each station functions as a relay, allowing the entire network to cover a large area. See **Figure 11**. This type of infrastructure can be decentralized (with no central server) or centrally managed (with a central server). Both are relatively inexpensive and very reliable. Individual mesh stations (nodes) act as repeaters to transmit data from nearby nodes. The reliability comes from the fact that each node is connected to several other nodes. If one node drops out of the network, due to hardware failure or any other reason, its neighbors simply find another route. Capacity can be increased by simply adding more nodes. Mesh networks constructed using HSMM nodes are known as HSMM-MESH or Broadband-Hamnet (www.broadbandhamnet.org).

5.1 A Basic HSMM **Radio Station**

For the sake of simplicity, we'll discuss an HSMM setup with two stations operating in a host/client configuration. See **Figure 12**.

At the time of this writing, the most popu-

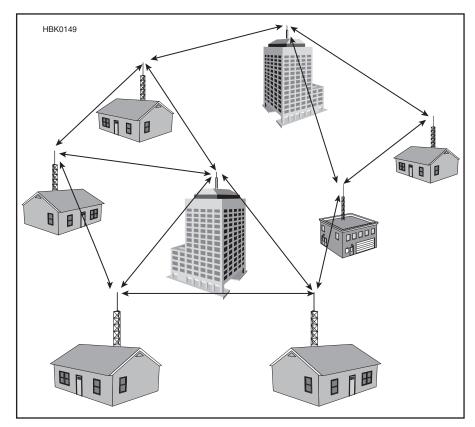

Figure 11 — An HSMM Mesh, or Broadband-Hamnet, network is highly decentralized. Individual mesh stations (nodes) act as repeaters to transmit data from nearby nodes. If one node drops out of the network, the other nodes will automatically re-route the traffic.

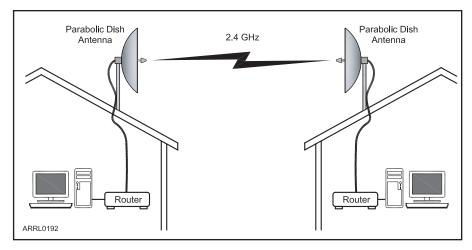

Figure 12 — This is a simplified diagram of a typical HSMM link between two stations. Note that high gain parabolic dish antennas are being used in this example.

Figure 13 — RP connector adapters.

lar wireless router for HSMM applications is the Linksys model WRT54GL. It is a combination unit consisting of a wireless access point (AP) or hub coupled with a router. As with other routers, your host PC or laptop connects directly to it using a standard Ethernet cable. If the PC is also connected to the internet, then it may also perform the function of a *gateway*.

The WRT54GL is a Linux-based model that supports firmware upgrades. HSMMactive amateurs have been creating their own WRT54GL firmware to support special applications (such as mesh networking). They are effectively "modifying" the WRT54GL in ways Linksys could not have imagined! You do not have the use a WRT54GL to explore HSMM, however. Any wireless router will do. The advantage of the WRT54GL is only that it is widely available and easily modifiable.

The first step in configuring your router for HSMM is to disconnect both flexible antennas that came with the unit and replace them with a high-gain directional antenna system. To connect a gain antenna, you are going to be become familiar with RP (reverse polarity) connectors. These connectors appear to be male connectors on the outside, but they have a socket rather than a pin for the center conductor. RP connectors are used by the manufacturers to discourage Part 15 owners from using the equipment in ways for which it was not WiFi certified.

As licensed radio amateurs, we can modify the system to accomplish our specific requirements within the amateur bands. To connect coaxial cable for an external antenna, you can use an adapter or short jumper cable assembly with appropriate connectors. The adapter shown in Figure 13 has an RP connector on one end and a standard SMA connector on

There are often two antenna ports on wireless devices. These are used for receive space diversity. The wireless device will normally automatically select whichever antenna is receiving the best signal at any specific moment. Which do you connect to?

The transmitted signal from the wireless router always goes out the same antenna port. It does not switch. In other words, most wireless devices use space diversity on the receive side and not on transmit. Some access points/ wireless routers will allow you to manually (via software) select the antenna port that is used for transmission. When there is no obvious choice, you will need to find some means of detecting which antenna is the transmit antenna port with RF output power present. That is the port to connect to your gain

Be sure to use low-loss coaxial cable, and keep the run as short as possible. Coaxial

cable loss at these frequencies can be quite high, so you are often better off mounting the router directly at the antenna, connecting to it through a very short length of cable. From there you can run the Ethernet cable back to your computer.

SOFTWARE CONFIGURATION

You will need to use either the network configuration software from the router manufacturer or the configuration tool that is part of your operating system. Some routers offer user-friendly access through internet browsers, which is particularly convenient. Regardless of the approach, the goal is to access and change your router's settings.

SSID: The AP/wireless router host software is provided with an SSID (Service Set Identifier) that many Part 15 stations turned off for somewhat higher security. But radio amateurs should leave it ON. Enter your call sign as the SSID and use it for the station identification. It constantly broadcasts your call thus, providing automatic and constant station identification. There are 32 characters available for use in this field so more information such as your group's name can be entered too, including spaces and punctuation. If the router asks if you want to enable the broadcast, click YES. (Note that SSID in the HSMM world has a somewhat different meaning than SSID in the packet radio community. Among packet users, SSID is defined as Secondary Station Identifier.)

ESSID: Some manufacturers use this term in place of SSID to put emphasis on the fact that the SSID is the name for your network, not for a specific wireless AP/router.

Access Point Name: When this field is made available (by default is it blank) it is for you to enter a description. This may be handy if you have deployed more than one AP in your network all with your call sign as the SSID. It would allow you to tell them apart. Otherwise, just leave it blank.

Channel: To avoid interfering with other services as much as possible, we need to also look at channel selection. Most HSMM activity is concentrated on 2.4 GHz, using channels 1 through 6, which are within the 2.4 GHz ham allocation.

It is probably best to avoid channel 6. It is the most common manufactures default channel setting and 80% or more of your neighbors will be using it for their household wireless local area network (WLAN). Channel 1 is used by most of the remaining manufacturers as their default channel, so avoid that too. The result is most radio amateurs use channels 3 or 4 depending whether there is a WISP (Wireless Internet Service Provider) operating in their area. Often a WISP will use one of these intermediate channels with a highly directive antenna for back-haul or other purposes. If so, you may wish to coordinate with the WISP and arrange to use some other channel rather than the one specifically used by the WISP. It is not a perfect solution because of all the overlap, but it is a good faith effort to keep most of your stronger signal out of anyone's home, business or governmental WLAN traffic.

WEP: This stands for Wired Equivalent Privacy. Despite all the horror stories you may have read in the press, this encryption method provides more than adequate means to economically achieve authentication and thus keep most free-loaders off your network. If you live in the country you may not need to enable this capability. In an urban environment, it is probably a good thing to do so that you need not constantly monitor every bit of traffic coming over the network to ensure that it originates from an Amateur Radio station. Mixing traffic with another service that shares the same frequency band is not a generally accepted practice except in times of emergency. Therefore, it is often necessary for HSMM radio stations to encrypt their transmissions. This is not to obscure the meaning of the transmission or hide the information. In amateur HSMM applications, the purpose of using WEP is only to block access by nonhams. Amateur HSMM net-works openly publish their encryption keys for other hams

Most wireless routers will allow for the use of multiple WEP keys, typically up to four. This will allow you to configure the device so that different client stations have different access authority. For example, club members may have one level of access, while a visiting radio amateur may be given a lesser access. Most HSMM radio groups have just one WEP key and everybody gets that one.

Remember that when it comes to the length of the WEP or other key used, our main purpose is to provide a simple and economical means of authentication already available on the wireless devices. In other words, it is to ensure that only Part 97 stations and not Part 15 stations auto-associate or auto-connect with our HSMM radio node. The shorter the WEP key, the better. This makes it easy to use and remember. During early HSMM radio experimenting around the year 2000, the shortest possible key (5 characters) was used:

Authentication Type: Some routers will ask for the type of authentication you want to use such as shared key, open system, and both. Click on SHARED KEY because you will be sharing the WEP/WPA key with all radio amateurs who wish to access your HSMM radio node.

DHCP: Some routers will ask if you want Dynamic Host Configuration Protocol enabled. This is the function that assigns IP addresses. Unless you have another source of the DHCP function on your network, you will want to ENABLE this function.

Antenna Selection: A few wireless routers with dual antennas will ask you select an antenna. The default is normally receive space diversity. Because we are going to connect an outside gain antenna, you want to make a selection. Otherwise, you will need to identify which antenna is the actual transmit antenna and connect the feed line to that port, as discussed previously.

Mac Address Filter: Some wireless routers will allow for this security measure, but it is troublesome to administer it, so it is recommended that you not bother enabling this function. Use WEP or some other method of encryption using the guidelines discussed previously.

Output Power: Some wireless routers will allow you to set this power level, often up to 100 mW. As with all other radio amateur operations use only the minimum power needed to accomplish your mission.

THE FAR END OF THE LINK

The computer at the client end of the HSMM link need only have a wireless networking adapter, not a separate router. These transceivers/wireless adapter cards usually come in three forms:

- 1) One form is called a PC card. Earlier these were called PCMCIA cards, but more recent terminology is to simply call them laptop PC cards.
- 2) Another type of transceiver/adapter comes with a USB interface, such as the one shown in Figure 14. This is often considered a superior interface for most HSMM stations. The reason for this has nothing to do with the quality of the transceiver, but rather the fragile nature of the tiny connectors found on PC cards. They are not really designed for frequent plugging and unplugging. Without extreme care, they can be easily torn out.
- 3) Linksys and other manufactures also produce similar cards for the expansion slot on the rear of your desktop PC too.

Regardless of the device you choose, it must have an antenna that is removable or has an external antenna port of some type.

To connect to the AP/wireless

Figure 14 — At the client end of the HSMM link, a simple wireless adapter will do. This USB model allows the user to remove the flexible antenna.

the wireless computer user(s) at the far end must exit ad-hoc mode and enter what is called the infrastructure mode, in their operating software. Infrastructure mode requires that you specify the radio network your computer station is intended to connect to (the host station's call sign), so set your computer to recognize the SSID you assigned to the AP/ wireless router to which you wish to connect.

As described previously, you may need to use an adapter to connect the card or interface antenna connector to the coaxial cable running to the antenna. At the other end, most 2.4 GHz antennas come with a standard female N-series connector.

Team up with a nearby radio amateur to test. Do your initial testing in the same room together making sure the link-up is working. Then as you increase distances going toward your separate station locations, you can coordinate using a suitable local FM simplex frequency. You will increasingly need this communication to assist with directional antenna orientation as you get farther apart.

5.2 Running High Power

It is tempting for some radio amateurs to think that if they run higher power they will get better range out of their HSMM radio station. This is not always the case. There are many factors involved in range determination when operating at 2.4 or 5.8 GHz. The first and most significant of these is the lay of the land (topology) and path obstructions. Running additional power is unlikely to correct for either of these impediments.

Second, running higher power to improve signal link margins often requires that this be done at both ends of the link to obtain meaningful results.

Third, most RF amplifiers for use with 802.11 are of the BDA (bidirectional amplifier) type, such as the one shown in Figure 15. They amplify both the incoming signal and the outgoing signal, and to get maximum effectiveness out of such devices they must be mounted as close as possible to the antenna.

Fourth, 802.11 signals from such inexpensive broadband devices often come with significant sidebands. This is not prime RF suitable for amplification. A tuned RF channel filter should be added to the system to reduce these sidebands and to avoid splatter.

Also, if your HSMM radio station is next door to an OSCAR satellite ground station or other licensed user of the band, you may need to take extra steps to avoid interfering with them, such as moving to channel 4 or even channel 5. In this case a tuned output filter may be necessary to avoid not only causing ORM, but also to prevent some of your now amplified sidebands from going outside the amateur band, which stops at 2450 MHz.

Do not use higher power as a substitute for

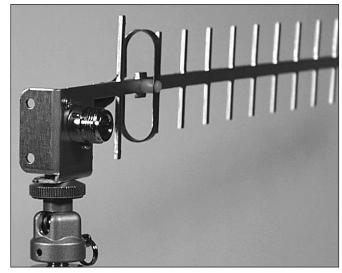

Figure 16 — Directional antennas, such as this MFJ 2.4 GHz Yagi, are best for HSMM links.

higher antenna gain at both ends of the link. Add power only after all reasonable efforts have been taken to get the highest possible antenna system gain and directivity.

5.3 HSMM Antenna Options

There are several factors that determine the best antenna design for a specific HSMM radio application. Most commonly, HSMM stations use horizontal instead of vertical polarization because it seems to work better. In addition, most Part 15 stations are vertically polarized, so this is sometimes thought to provide another small barrier between the two different services sharing the band. With multipath propagation is it doubtful how much real isolation this polarization change provides.

More importantly, most HSMM radio stations use highly directional antennas (Fig**ure 16**) instead of omnidirectional antennas. Directional antennas provide significantly more gain and thus better signal-to-noise ratios, which in the case of 802.11 modulations means higher rate data throughput and greater range. Higher data throughput, in turn, translates into more multimedia radio capability. Highly directional antennas also help amateurs avoid interference from users in other directions.

6 Automatic Link Establishment (ALE)

Automatic link establishment (ALE) is a "system" that incorporates digital techniques to establish a successful communications link. ALE is not a digital mode per se, but the primary software is sound device based.

To understand ALE, consider how HF propagation changes. A band can open over a path one hour, but close the next. A signal may be fully readable on one band, but inaudible on another. With that in mind, imagine two stations, one in New York City and one in Los Angeles, that wish to communicate on the HF bands (see Figure 17). Basic propagation guidelines give a general idea of which bands might be best, but operators at both ends of the path will have to experiment, calling on several bands until they find a frequency that supports a transcontinental path.

ALE automates this process, allowing the stations under computer control to automatically call each other on different bands until contact is established. In the example, the operator in New York City initiates the ALE call by entering the call sign of the receiving station into his ALE software, along with some likely frequencies. The call sign becomes the Selective Call, or SELCAL. The ALE software switches the transceiver to the first frequency in the queue and transmits the chosen SELCAL. If there is no response, the software will step the transceiver to another frequency and try again.

At the same time, the receiving station in

Los Angeles has been automatically scanning specific ALE frequencies, listening for its call sign. When it finally decodes something that resembles its call sign, it stops scanning and listens since the ALE data burst contains several repetitions of the call. When it finally decodes its full call sign, the Los Angeles

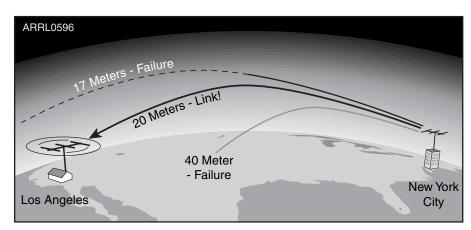

Figure 17 — The ALE calling station typically scans through a list of frequencies, calling on each one until a path to the receiving station is found.

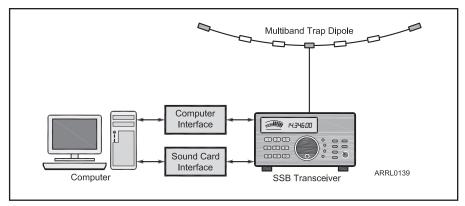

Figure 18 — An optimum ALE station has a computer-controlled transceiver and a multiband antenna system. In this example, the station is using a multiband trap dipole antenna. Note that a separate interface is needed between the computer and transceiver for frequency control.

station transmits a "handshake" signal to the New York City station to confirm that a link has been established. All scanning stops and the ALE software sounds an alarm to call the operators to their stations.

ALE is a good tool for HF net operation in both routine and emergency applications where many stations may be standing by for calls. Think of ALE as being analogous to a VHFFM scanning transceiver with a digitally coded squelch that automatically scans several repeaters. Unless it hears the correct code,

the radio remains silent. With amateur ALE you can call individual stations or entire groups of stations.

In addition to its application as a selective calling system for HF voice, ALE can also be used as a pure digital mode for exchanging text and images.

AMATEUR ALE SOFTWARE

ALE has been used by the military and government for years, and hams have generally adopted the government ALE standards: FED-STD-1045 or MIL-STD 188-141. In 2001, ALE captured the attention of the Amateur Radio world with the release of PCALE software by Charles Brain, G4GOU. PCALE not only controls your transceiver, it uses your computer sound device to decode ALE signals and generate them for transmission. You'll find PCALE software online at www.hflink.com. From the standpoint of assembling a station for ALE, it works best when two conditions are satisfied: 1) you have a multiband HF antenna system; the more bands the better; and 2) your HF transceiver can be controlled by computer.

Although you can use ALE on just one frequency, the real power of ALE comes into play when your station is able to operate on multiple bands under computer control. A typical setup is shown in Figure 18 and includes a radio control interface as well as a sound device interface. With PCALE controlling your radio, it will automatically change frequencies, monitoring as many bands and frequencies as you have programmed into the software. A list of ALE channels and information on ALE nets is available from www.hflink.com. Note that all ALE transmissions use USB. ALE must be used in accordance with the rules for stations operating automatic control.

7 D-STAR

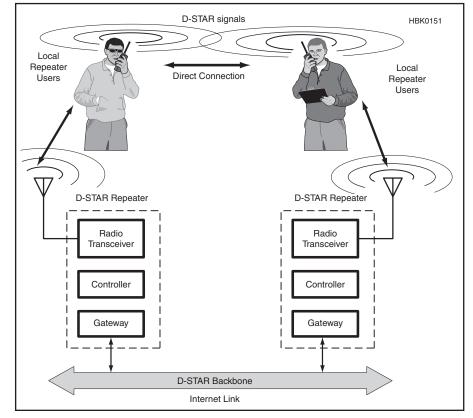

The D-STAR digital protocol began in 2001 as a project funded by the Japanese Ministry of Posts and Telecommunications to investigate digital technologies for Amateur Radio. The research committee included representatives of the Japanese Amateur Radio manufacturers and the Japan Amateur Radio League (JARL). JARL is the publisher of the D-STAR protocol.

All radio manufacturers are free to develop D-STAR equipment, but at the time of this writing Icom and Kenwood are the only companies that have done so for the US amateur market. Neither company "owns" the original D-STAR protocol.

7.1 What is D-STAR?

The primary application of D-STAR is digital voice, but the system can handle any sort of data — including text, voice or images. As shown in Figure 19, a D-STAR network

Figure 19 — A D-STAR network can take several forms. D-STAR compatible transceivers can communicate directly (simplex) or through a D-STAR repeater for wide coverage.

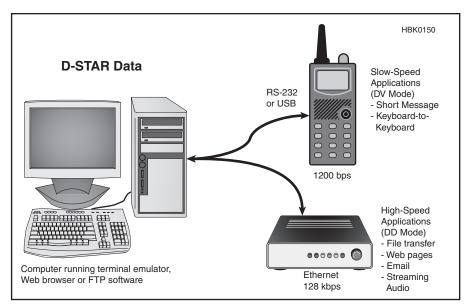

Figure 20 — Radios that support DV voice and data present an RS-232 or USB 2.0 interface to the user.

can take several forms. D-STAR compatible transceivers can communicate directly (simplex), or through a D-STAR repeater for wide coverage. D-STAR signals cannot be repeated through traditional analog repeaters without modification.

The D-STAR system carries digitized voice and digital data, but does the job in two different ways. There is a combined voice-anddata mode (DV) and a high-speed data-only stream (DD). From the perspective of the D-STAR user, data and voice are carried at different rates and managed in different ways, but over the air they are transported as bit streams.

7.2 Digital Voice and Low-Speed Data (DV)

The D-STAR codec digitizes analog voice by using the AMBE 2020 codec. AMBE stands for Advanced Multiple Band Encoding and 2020 designates the variation used by D-STAR.

AMBE can digitize voice at several different rates. The D-STAR system uses a 2.4 kbit/s rate that offers a good compromise between intelligibility and the speed at which data must be transmitted via the radio link. In addition, AMBE adds information to the voice data that allows the receiving codec to correct errors introduced during transmission. The net result is that the digitized voice stream carries data at a rate of 3.6 kbit/s.

Interleaved with the digitized voice information, D-STAR's DV mode also carries 8-bit digital data at 1200 bit/s. This data is used for synchronization in the D-STAR protocol with the remaining bandwidth available

for use by the radio manufacturer. Icom uses the remaining bandwidth to carry repeats of the D-STAR RF header, the 20-character front-panel message, and serial data as described below.

Radios that support DV voice and data provide an RS-232 or USB 2.0 interface to the user as shown in Figure 20. (The RS-232 interface is restricted to RxD, TxD and ground - "three-wire" connection.) Any computer terminal or program that can exchange data over those types of interfaces can use D-STAR's DV mode capabilities as a "radio cable."

Because D-STAR's DV mode handles the data stream in an unmodified "raw" format. it is up to the equipment or programs that are exchanging data to manage its flow.

7.3 High-Speed Data (DD)

D-STAR's high-speed data mode is called D-STAR DD. This mode does not digitize the analog voice signal. The data-only packets sent over the RF link at a raw data rate of 128 kbit/s half-duplex, but since that includes the packet header and the delay between packets, the *net data rate* is somewhat lower. As with the DV mode, data is transmitted without modification so flow control is left to the applications on each end. Radios supporting DD mode communications may also support DV mode.

Users connect to a radio supporting DD mode with an Ethernet interface via the usual RJ-45 modular jack found on computer networking equipment. The DD mode interface looks to computer equipment just like a customary IP network connection. Specifically, the DD mode interface is an Ethernet "bridge." This allows web browsers and other internet software to run normally, as if they were connected to standard computer network.

The net data rate of DD mode is comparable to or better than a high-speed dial-up internet connection. Any streaming media mode that will run over dial-up internet will likely perform well over D-STAR.

With its high signaling rate and 130-kHz bandwidth, FCC regulations restrict D-STAR DD operating to the 902 MHz and higher bands.

7.4 D-STAR Radios

At the present time, Kenwood offers a single D-STAR-compatible handheld transceiver, the model TH-D74A, for 2 meters and 70 centimeters.

Icom D-STAR radios are available in several models as mobile/base transceivers and as handheld transceivers. Except for the ID-1 base/mobile transceiver, which operates at 1.2 GHz, Icom D-STAR transceivers are designed to operate at 2 m, 70 cm or both. Icom D-STAR transceivers also support both digital and analog operation, which means that they can also be used for traditional analog FM communication as needed. An example is shown in Figure 21.

To determine the most appropriate D-STAR radio for an application, the first step is to understand the requirements:

- Is DD mode operation required (highspeed data)? If so, the only radio supporting DD mode is the ID-1.
- What bands are required? That will depend on activity in your area. If data is to be transmitted while in motion, higher frequencies will result in fewer transmission errors, improving the net data exchange rate. (Note: DD operation is only permitted on 902 MHz and higher.)

Figure 21 — The Icom ID-51A is a 2 meter/70-cm handheld with D-STAR functionality.

- Is high-power required? Using higher power base/mobile radios will result in stronger signal strengths and fewer data transmis-
 - If data is to be transmitted, what data

interface does the computer have?

• Error correction for low-speed data (DV mode) is the responsibility of the data communications programs used to exchange data. Make sure to carefully evaluate the software you intend to use.

More information about D-STAR may be found in the Digital Protocols and Modes and Repeaters chapters of the ARRL Handbook.

8 DMR: Digital Mobile Radio

Digital Mobile Radio (DMR) is not new technology as such, but what is relatively new is its adoption by the Amateur Radio community. DMR's origins are in commercial and public service applications such as police, fire, and so on. Amateurs began re-purposing 2 meter and 70-centimeter DMR transceivers by simply reprogramming them for ham frequencies and they did the same with commercial DMR repeaters. Many DMR repeaters are linked to the internet, creating a global network. The result has been substantial growth in DMR activity during the last several years. In addition, at the time of this writing, several manufacturers were marketing DMR transceivers to the Amateur Radio market in recognition of its increasing popularity.

8.1 DMR Advantages

Digital Mobile Radio is spectrally efficient compared to other VHF/UHF digital modes.

A DMR repeater can support two simultaneous digital conversations within a 12.5 kHz bandwidth. The repeater achieves this by using TDMA - Time Domain Multiple Access – to rapidly switch between data channels. A DMR repeater has two available time slots, which means that two individuals can effectively use the repeater at the same time and on the same frequency. The switching is so rapid that the signals are repeated seamlessly and with little interruption. If both timeslots happen to be in use, users hear a "busy" beep when they attempt to transmit.

Another advantage is a DMR repeater's ability to support analog FM transmissions in addition to digital. This factor has given an additional boost to DMR adoption.

8.2 DMR TalkGroups

A DMR repeater will typically offer several TalkGroups and these are simply "chat rooms" that cover a state or region. Thanks to internet linking, TalkGroups can also span the globe. Different DMR repeaters link to different Talk Groups, so it helps to obtain this information from the hams who use your local repeaters.

8.3 CodePlugs and **Programming**

Unlike an analog FM repeater that just requires the frequency pair and possibly a CTCSS tone, a DMR repeater requires the user's transceiver to transmit the call sign and "Color Code" of the desired repeater. DMR transceivers must be programmed with this information using a data file known as a CodePlug. Fortunately, CodePlugs and programming software are easily obtainable online, often free of charge. The best approach is to contact local DMR users for assistance. They'll know where to find CodePlugs not only for DMR repeaters in your area, but also throughout the region in which you reside.

9 System Fusion

System Fusion is a proprietary C4FMbased digital system developed by Yaesu. The use of the word "fusion" is a reference to the fact that Fusion hardware is capable of detecting analog or C4FM digital signals and automatically switching from one mode to the other as necessary, effectively "fusing" analog and digital functionality. The analog/digital detection and switching is completely transparent to the operator and does not require operator action of any kind.

Thanks to the automatic switching function, a System Fusion repeater can replace an existing analog FM repeater with little impact on analog FM users. A Fusion repeater will repeat all analog signals, regardless of the type of transceiver that generates them. In fact, FM

users will not notice a difference except when the repeater is relaying a digital signal from a System Fusion transceiver. In that instance, analog users will hear a buzzing sound.

Unlike DMR or D-STAR transceivers, Yaesu System Fusion transceivers do not require elaborate programming beyond entering one's call sign when the transceiver is powered on for the first time. Using a Fusion transceiver with a Fusion repeater is as simple as squeezing the Push-To-Talk button. The "analog side" of a System Fusion repeater may require CTCSS tones in some instances and, of course, these would have to be programmed in the transceiver for analog

There are a variety of Yaesu System Fusion

transceivers and their capabilities differ from model to model, but all can switch from analog to digital automatically. A basic Fusion radio supports digital and analog FM, but usually includes higher and lower quality digital voice modes. (The higher quality mode consumes somewhat more bandwidth and may be more vulnerable to "drop outs" under margin signal conditions.) More expensive transceivers add the ability to send and receive images, among other data. They also provide access to the global Yaesu WIRES-X network through repeaters that linked to the internet.

More information about System Fusion may be found in the Digital Modes and **Protocols** and **Repeaters** chapters of the ARRL Handbook.

10 HF Digital Voice

While D-STAR is the dominant digital voice/data system on the VHF+ bands, two very different systems can be found in operation on the HF bands. One uses dedicated hardware while the other two rely on sound devices and software. All require HF SSB transceivers, although they could just as easily be used on VHF SSB (or even FM) as well.

10.1 AOR and AMBE

The AOR Corporation was the first ham manufacturer to arrive on the scene with an HF digital voice and data "modem" in 2004. The fundamental design is based on a Vocoder protocol created by Charles Brain, G4GUO. His protocol involves the use of Advanced Multi-Band Excitation, better known as AMBE, a proprietary speech coding standard developed by Digital Voice Systems. Brain's protocol operates at 2400 bit/s, with Forward Error Correction added to effectively produce a 3600 bit/s data stream. This data stream is then transmitted on 36 carriers, spaced 62.5 Hz apart, at 2 bits/symbol, 50 symbols/s using QPSK. This gives the protocol a total RF bandwidth of approximately 2250 Hz (compared to 2700-3000 Hz for an analog single sideband transmission).

The AOR units, such as the ARD9800 (Figure 22), are designed to be as "plug and play" as possible. You simply plug your microphone into the front-panel jack and then plug the modem into the microphone input of your transceiver. A front panel switch selects digital encoding or analog transmission, so the unit can be kept in the line when not used for digital conversations. On the receive side, the modem automatically detects the sync signal of an AMBE transmission and switches to digital mode automatically. In addition to voice, the AOR modems can send digital data (typically images).

AOR ON THE AIR

AOR digital voice is clear and quiet, an unusual thing to hear on an HF frequency. Tune around 14.236 MHz and you're likely to hear AOR AMBE signals. They sound like rough hissing noises.

During QST Product Review testing in 2004, the ARRL Lab discovered that decoding was solid down to about 10 dB S/N. Digital voice is an all-or-nothing proposition, however, and below that level the signals begin to break up. The result is absolute silence during those periods. Interference to the received signal produced a similar outcome.

The common approach on the air is to begin the conversation in analog SSB, then switch to digital. Each transmission starts with a onesecond sync burst after the push-to-talk button is pressed. If the other station misses the sync signal, the audio doesn't decode and the transmission sounds like analog white noise. This means that for successful communication you must be on the correct frequency and ready to receive at the beginning of the transmission. However, if there is fading or interference during the sync transmission, you may be

unable to decode the signal that follows.

A few additional steps will improve odds of success with AOR modems.

- Make sure that both stations are on the same frequency, within about 100 Hz.
 - Set IF receive filters to 3 kHz or wider.
 - Don't overdrive the modem audio input.
 - Turn off transceiver speech compression.
- Don't overdrive the radio. If the ALC meter shows any activity, turn down the output from the modem.

Transceiver duty cycle will be substantially higher when you're operating digital voice compared to normal SSB. To avoid damaging your radio, it is a good idea to reduce your output by 25 to 50%.

10.2 FreeDV

FreeDV is an open-source software-based HF digital voice system for Windows, Linux, or OS X (Figure 23). It is designed to use a computer sound device or on-board sound chipset to send and receive amateur digital voice. Activity is primarily on HF at 14.236 MHz. In addition to the software, you need a

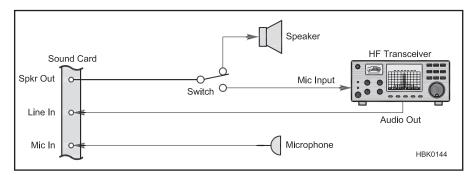

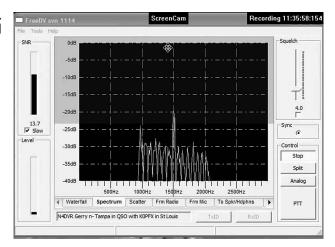

Figure 24 — The single sound device approach to using FreeDV requires the means to switch the audio stream when switching from transmit to receive.

Figure 23 — FreeDV digital voice software. [N9SJA photo]

Figure 22 — The AOR ARD-9800 digital voice modem.

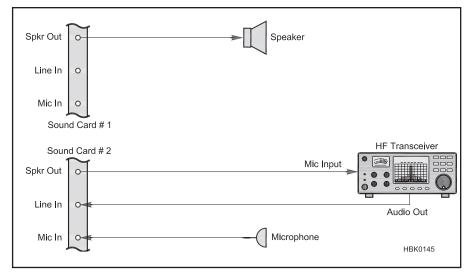

Figure 25 — The most elegant, easy-to-operate solution for *FreeDV* is to use two sound devices — one to process the received signal and the other to generate the transmit signal.

radio, computer and one of the sound-device interfaces discussed earlier in this article. Start by downloading and installing the *FreeDV* software at **freedv.org**. On this same website

you will find documentation that explains installation and operation.

To receive, all you need is a cable between the audio output of your radio and the LINE

INPUT of your sound device. You may need to get into your sound device control software and boost the LINE INPUT gain. If the signal in the waterfall display is too bright, reduce the gain control.

Transmitting with *FreeDV* is somewhat more complicated in terms of your station setup, especially if you have only one sound device. (**Figure 24**) The audio output from your sound device must be applied to your headset or PC speakers for receiving, but the *same* output must also feed your transceiver for transmitting, so a switch for the audio output is needed. The easier, more elegant approach is to use two separate sound devices. (**Figure 25**) The second sound device doesn't need to be high-end; you can use an inexpensive USB sound device for this application.

An alternative to the software and computer approach is available with the Rowetel SM1000 FreeDV adapter. The SM1000 integrates the entire FreeDV system within a handheld enclosure, allowing you to enjoy digital voice without a computer. At the time of this writing, the SM1000 was available for \$201 US. See www.rowetel.com for more information

11 EchoLink, IRLP and WIRES-X

Worldwide communication on HF requires reliable propagation and more substantial radio and antenna requirements than a basic VHFFM setup. By using internet links instead of HF radio links, a ham with a modest radio (even a handheld transceiver) can reliably communicate with stations hundreds or even thousands of miles away at any time of the day or night (Figure 26).

The most common form of amateur internet linking involves the exchange of audio using *VoIP* — Voice over Internet Protocol — technology. This is the same technology used by internet telephone services, and by online voice "chat" applications such as *Skype*, *TeamSpeak* and others. Three versions of Amateur Radio voice linking have become popular in the US: EchoLink, IRLP and WIRES-X.

11.1 EchoLink

EchoLink software, developed by Jonathan Taylor, K1RFD, is designed for Windows PCs, but there is a Mac version as well. With the software installed on a sound-device-

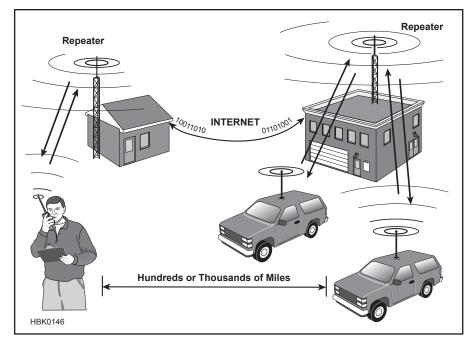

Figure 26 — The internet VoIP link allows repeater users to speak with other amateurs who may be transmitting through other repeaters.

equipped computer, any ham can create an EchoLink node that others can access by radio. Hams can also join the network directly without using radios. They simply plug microphone/headsets into their computers.

Each EchoLink node is assigned a number that can be up to six digits in length. RF users access the EchoLink network by first sending the DTMF code required to activate the link on a repeater or simplex node. (Figure 27) Of course, this requires a transceiver equipped with a DTMF keypad. Once the link is up, they use the keypad again to transmit the number of the EchoLink repeater, link or user they wish to contact.

Hams who access the network directly (without a radio) select the person or system they wish to contact by simply clicking on its name in the software listing (Figure 28). The EchoLink network maintains continuously updated databases on several servers that indicate node and user locations and operational status. The network servers also support *con*ferencing where many users can "meet" and speak together, either by direct access or via radio.

EchoLink supports communication among three different source groups:

• Repeaters: This is typically a VHF/UHF FM repeater with a computer at the site and a VoIP connection to the internet via EchoLink. When the EchoLink function is switched on, audio from the repeater is available on the EchoLink network, and vice versa. The internet VoIP link allows repeater users to speak with other amateurs who may be transmitting through other repeaters, or who may be linking directly.

- Links: Similar to repeater nodes, but operating on simplex frequencies without full repeater functionality. These are typically FM transceivers connected to computers. Depending on the station setup, their coverage can be confined to a neighborhood, or it may encompass an entire county.
- Users: This is strictly a computer-tocomputer VoIP connection with no RF involved. In other words, the operator is sitting in front of his computer wearing a microphone/headset.

All the interfacing on the "RF side" of EchoLink is handled by connections to the computer sound device and serial port with a sound-device interface used to switch the radio between transmit and receive - the same setup used by sound device based digital communications such as PSK

ECHOLINK SECURITY

Before being granted access, every ham who establishes an EchoLink node, or who connects to the network directly, must provide positive proof of identity and license during the EchoLink registration process. After having been validated, each EchoLink node or user must provide a password, along with his or her call sign, to log in. Each time a connection is made for a QSO, the EchoLink servers verify both the sender and the receiver before communication can begin. Hams who use their radios to connect to the EchoLink network through a repeater or a simplex node do not have to be validated or provide a password. This is only necessary for the repeater or link stations, or for those who connect directly.

It is possible to configure EchoLink to accept connections only from certain types of stations: repeaters, links, users or all three. You can also set up a list of any number of "banned" call signs, which will not be allowed access. In addition, you can block or accept connections according to their international call sign prefix, to comply with reciprocal control-operator privileges or third-party traffic restrictions.

In Sysop mode, by default, EchoLink announces each station by call sign when the station connects. (The user can program a voice or CW ID that is generated automatically when needed.) The EchoLink software automatically generates detailed logs and (optionally) digital recordings of all activity on the link.

Unlike software such as e-mail programs, file-sharing programs and web browsers, EchoLink does not have any way to pass files or "attachments" that might harm your computer. There are no known cases of EchoLink

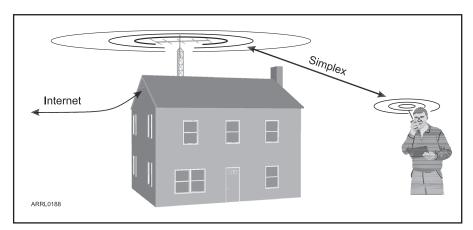

Figure 27 — A typical EchoLink simplex node.

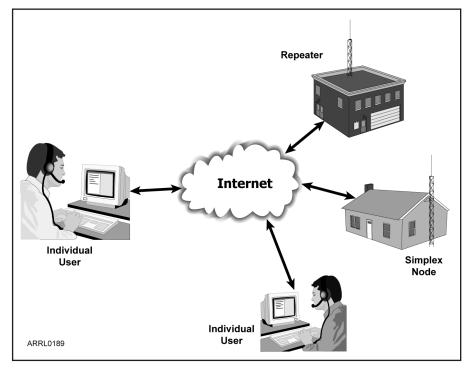

Figure 28 — For some EchoLink users, there is no radio involved (at least at their end of the conversation).

accepting or spreading a computer virus. Of course, any PC connected to the internet should always be protected by some sort of internet security hardware or software.

11.2 IRLP

IRLP stands for Internet Radio Linking Project. Like EchoLink, IRLP uses the internet to establish VoIP links. The difference is that IRLP only permits access via RF nodes at repeaters or on simplex frequencies (all IRLP nodes are interlinked via a central internet server). You must use a radio to access the IRLP network.

A typical IRLP node consists of a transceiver that is connected to the internet through dedicated IRLP hardware and software. This requires a Linux computer running IRLP software and an IRLP interface board, or a turnkey "embedded" IRLP unit that combines the Linux computer, IRLP software and interface in a single package. The IRLP software controls the VoIP audio stream using carrier operated squelch (COS) or continuous tone coded subaudible squelch signals (CTCSS) from the transceiver. When COS is present, the computer detects it through the IRLP interface board.

The operator connects to the IRLP network (at a repeater, for instance) using DTMF signals sent over the radio. As with EchoLink, this means that the operator must have a radio with a DTMF keypad. The actual access code is determined by the owner of the node. The user sends the correct DTMF sequence to bring up the IRLP connection, then sends the sequence of the distant node he wishes to contact. That might be a repeater in another state or a distant simplex node. You can view a list of current IRLP nodes at status.irlp.

Here is an example of a typical IRLP con-

- Press the transceiver PTT and identify your station. For example, "This is WB8IMY, Steve in Wallingford, Connecticut, USA connecting to node 8880."
- Next, press #8880 (node 8880 in this example) on the DTMF keypad, release PTT and wait for the node connect announcement. The announcement indicates that your audio is now reaching the distant node. You can call a specific person, or just ask if anyone is around to chat.
- When finished, key PTT, make an announcement such as "WB8IMY releasing node 8880" and then press #73 on the DTMF keypad to disconnect. The IRLP node will announce the disconnect and the node may now connect to a different node, reflector, or it will stand by awaiting another user.

It is interesting to note that there is a project underway (known as EchoIRLP) to bridge the IRLP and EchoLink networks.

11.3 WIRES-X

WIRES-X — Wide-Coverage Internet Repeater Enhancement System — is a VoIP network created by Vertex Standard (Yaesu). It is functionally like IRLP (including management via a central internet server), but nodes and repeaters are connected via a Vertex Standard HRI-100 interface and a computer running under the Windows operating system. Vertex Standard transceivers are *not* required for WIRES-X communication, but as with IRLP, all access must be via RF. WIRES-X also supports the Yaesu System Fusion network of repeaters for automatic routing and many other features.

There are two WIRES-X operational configurations using home stations (simplex nodes), repeaters or a combination of the two:

SRG — Sister Radio Group. You operate within WIRES-X in a small (10 node maximum) network that is ideal for closed-group operations. Within the network, all nodes operate using the same repeater node list, so you can link only to stations within this 10-node network. Because there are only ten nodes maximum, access to any of these nodes is possible using a single DTMF tone when calling. At the beginning of each transmission, this single DTMF tone locks communication between the calling node and the called node, but local (non-linked) transmissions are also possible, simply by omitting the DTMF tone at the beginning of the transmission.

FRG — Friends Radio Group. You may call any repeater registered with the WIRES-X FRG server. In the case of FRG operation, a six-digit DTMF code is required for access, and once the link is established this code need not be sent again (this is called the LOCK mode), unless the operator wants the ability to make non-linked transmissions (UNLOCK mode), in which case the six-digit code must be sent at the beginning of each transmission (using the DTMF Autodial feature of the transceiver, for example). Group calling to preset 10-repeater B, C, and D lists is also

SRG is similar in philosophy to the local FM voice repeater where you tend to talk to the same group on a regular basis. FRG is similar in concept to IRLP, linking together a worldwide group of repeaters and base stations.

Image Communications

This supplement covers two popular communication modes that allow amateurs to exchange still or moving images over the air. Advances in technology have made image communications easier and more affordable, resulting in a surge of interest.

The first part of this chapter. updated for this chapter by Tom O'Hara, W6ORG, describes fastscan television (FSTV), also called simply amateur television (ATV). ATV is full-motion video over the air, similar to what you see on your broadcast TV. Because of the wide bandwidth required for ATV signals, operation takes place on the UHF and microwave bands.

The second part of this chapter, updated by Larry Peterson, WA9TT, describes slow-scan television (SSTV). Instead of full motion video, SSTV requires from 8 seconds for a black-and-white image to 1-2 minutes for a full-color image. SSTV is a narrow bandwidth image mode designed to use voice transceivers SSB on the HF bands and FM on VHF and higher frequencies. SSTV is also supported by repeaters, satellites, and the ISS.

Unless otherwise noted, references to other chapters refer to chapters in the print version of the ARRL Handbook.

1 Fast-Scan Amateur Television Overview

Fast-scan amateur television (FSTV or just ATV) is a wideband mode that is based on the analog NTSC (National Television System Committee) standards used for broadcast television in the US for many years, before most broadcasters switched to digital transmission in 2009. Analog AM and FM ATV use standard NTSC television scan rates. It is called "fast scan" only to differentiate it from slow-scan TV (SSTV) or digital TV (DTV). In fact, no scan conversions or encoders/decoders are necessary with analog ATV.

Any standard TV set capable of displaying analog NTSC broadcast or cable TV signals can display the AM Amateur Radio video and audio signals. Since 2008, new consumer digital television (DTV) sets sold in the US are designed to receive high definition television (HDTV) broadcasts using the 8-VSB (8-level Vestigial Side Band) standard from the Advanced Television Systems Committee (ATSC). DTV televisions also include analog AM and Digital Cable (D-CATV) channel tuners and cable quadrature amplitude modulation (QAM) tuners per FCC Rule 15.118(c). It is a good idea however, to not dispose of your old analog-only televisions, but keep them for ATV. Analog AM ATV on the 70 cm band will be the primary ATV system for some time given its low cost, size, and ease to get on.

To transmit ATV signals, standard RS-170 composite video (1-V peak-to-peak into 75Ω) or 480i/30 NTSC and line audio from home camcorders, cameras, DVD/VCRs, DVRs, or computers is fed directly into a transmitter designed for the ATV mode. The audio goes through a 4.5 MHz FM subcarrier generator in the ATV transmitter that is mixed with the video. It is the same for FM ATV, but the sound subcarrier can be anything from 4.5 MHz to 6.8 MHz, with 5.5 MHz typical.

Picture quality is about equivalent to that of a VCR, depending on video signal level and any interfering carriers. All of the sync and signal-composition information is present in the composite-video output of modern cameras and camcorders. Most camcorders have an accessory cable with RCA phono plugs that provide separate audio/video (A/V) outputs. Security video cameras with A/V plugs or noted as CVBS (composite video baseband signal) are also popular. Analog HD, HDcctv, HD-TVI, AHD, HD-SDI, IP or other cameras use different video standards and cannot be used for analog NTSC ATV unless they first go through a conversion in a DVR or other device. Audio output may vary from one camera to the next, but usually it has been amplified from the built-in microphone to between 0.1 and 1 V P-P (into a 10-k Ω load).

1.1 ATV Activities

Amateurs regularly show themselves in the shack, zoom in on projects, show home video recordings, televise ham club meetings and share just about anything that can be shown live or recorded (see Figures 1 and 2, application notes at www.hamtv.com/info.html, and www. **kh6htv.com/application-notes**). Whatever the camera "sees" and "hears" is faithfully transmitted, including full motion color and sound information. Computer graphics and video special effects are often transmitted to dazzle viewers. Several popular ATV applications are described in detail later in this chapter.

Figure 1 — Students enjoy using ATV to communicate school to school or between classrooms (top). The ATV view shows the aft end of the Space Shuttle cargo bay during a mission (bottom).

Figure 2 — The one-way ATV DX record is held by KC6CCC in San Clemente, California, for reception of 434-MHz video from KH6HME in Hawaii during a tropo opening in 1994. The distance is 2518 miles. See www.hamtv.com/atvdxrecord. html.

1.2 Comparing Analog AM, FM and Digital ATV

Receiving ATV using any of the three ATV modes is relatively easy using consumer televisions and receivers directly, or with the addition of an amateur band receive converter (downconverter). Much of the activity in an area depends on the first few hams who experiment with ATV, and on the cost and

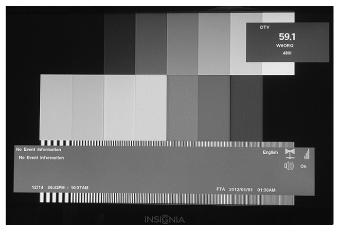

Figure 3 — When the info or display button is pushed on newer digital TV's remote control, the D-CATV channel number may be a Virtual Channel designation from 1 to 999 (and not the actual transmitted channel programmed in the DTV modulator), along with the station call and other information. Channel 59.1 is shown, but the actual transmitter channel was 58 and does not change if the frequency is changed. Analog channels are shown without the decimal point or with a decimal point or dash and a zero. Digital channels are shown with a major number, decimal point or a dash and a minor number. The minor numbers indicate that this channel may have more than one video or program.

availability of equipment for others to see their first picture.

Most older analog-only TVs that do not have active channel memory scan setup and don't have video squelch that goes to blank or blue screen when no signal is present are preferred by ATV DXers as they can continuously search or monitor for ATV signals in the snow easily. Newer TV's have an active channel scan setup that searches for analog and digital channels and skips those that are found not to be active. If you have cable, most likely it will have active cable channels 57-60 (direct 70 cm ATV), 3 and 8 (downconverter output) and be available for use on ATV if you have done the setup scan while connected to your cable service. If you do not have a cable service, your TV may or may not let you manually add a channel if no signal is present. You may have to get a local ATVer to send you a signal that is strong enough as you do the channel scan. This will also be the case with over the air digital 8-VSB and cable QAM transmissions. DVB-T and DVB-S will require a receiver or set top box connected to your newer TV's HDMI monitor input, and also require an active channel scan.

The frequency reference for an analog AM transmission is the video carrier which is 1.25 MHz up from the lower channel edge. A digital transmission is referenced as the center frequency — for instance, cable channel 57 AM is 421.25 MHz, digital is 423.0 MHz in the same 420-426 MHz range. Note that D-CATV stations can present as Virtual Channels or Logical Channel Numbers which

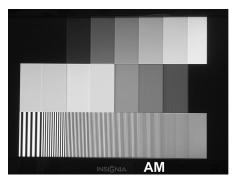

may not be the actual transmitted channel when detected by the TV setup channel scan. If your TV info overlay says you have a valid digital channel 59.1, it could actually be transmitted on a different channel. The station ID, channel and info are transmitted with the video and any text can be programmed into the modulator as seen in **Figure 3** for whatever purpose the cable operator has.

Analog AM TV on the 70 cm band is the easiest mode to get on and can be found with the weakest signal. The 70 cm ham band contains the same frequencies as analog cable channels 57 through 61 which makes it practically no cost, other than a 70 cm antenna, to see your first AM ATV picture. Simple 70 cm ATV transmitters are available that are low cost, small, and draw less current than the other ATV modes. This is desirable for R/C (radio control), high altitude balloon, rocket and portable emergency communications or public service events. Call letter IDs with 70 cm AM ATV can be seen at much greater range, although with a lot of snow in the picture, and is the favorite of DXers. Adding a linear amplifier requires an initial drive setup so as to keep the video modulation within the linear range.

FM ATV also uses simple transmitters, but most activity is on the 13 cm, 23 cm and 33 cm amateur bands. This is in part because of the wide occupied bandwidth needed for FM ATV signals, and in part because of the availability of receivers originally designed for commercial C-band satellite or unlicensed Part 15 use. The FM receivers have analog

Figure 4 — The Hi-Des HV-100EH DVB-T modulator is shown here driving a KH6HTV 70-7B linear amplifier on the 70 cm band. The modulator also tunes the 33 cm band and has an adjustable output up to -3 dBm for driving a high linearity MMIC and FET power amplifier. Transverters can be used for operation on the higher frequency bands.

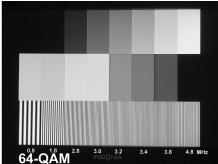

Figure 5 — These two images compare P5 test patterns from an AM analog transmitter and a D-CATV 64-QAM transmitter. The 4.8 MHz multiburst vertical lines can be seen in the 64-QAM 480i picture ,but the AM is rolled off to grey and is limited to resolving the 3.8 MHz burst lines

A/V outputs that must be connected to a video monitor and not a channel 3 analog RF modulator to a TV in order to see the best picture resolution possible. Less care need be given to driving power amplifiers than when using AM or digital modulation.

Digital Video Broadcast-Terrestrial (DVB-T) set for 2, 4 or 6 MHz QPSK has become the preferred digital ATV mode because it takes the least signal level to lock in the picture. Equipment for this DTV mode has become available at lower cost than the others. Set top box receivers can be found on the internet at low prices, but most need a good preamp, will not receive 2 or 4 MHz modulation and some tuners cannot be made to lock on to the 70 cm ham frequencies without a downconverter. Modulators are available for DVB-T the ham bands (Figure 4). RF amplifiers for DTV however, are more critical as to drive level, linearity and low inter-modulation distortion than with analog AM or FM ATV modes. DVB-T does well with motion and multipath among the DTV types. High definition 1080p video can be run in a 6 MHz channel and 480i in a 2 MHz channel. However, 1080p can also be run in a 2 MHz channel but pixilation, freezing,

smearing and longer latency can occur depending on motion and how many pixels are changing. DTV can have higher resolution (Figure 5) than AM because they do not have a sound subcarrier that limits the video bandwidth.

Cable Quadrature Amplitude Modulation —(QAM) is easy to receive with newer TV's since 2012, but requires the most signal strength of the DTV modes. Cable QAM (D-CATV) uses the North American ITU-T J.83B protocol which is different in the USA compared to Digital Video Broadcast - Cable (DVB-C) in most of the rest of the world. Cable head-end modulators such as the Drake DSE24 are available and prices have been coming down.

ATV running Digital Video Broadcast-Satellite (DVB-S) often uses "free to air" receivers made for satellite TV reception in Europe and other parts of the world and can be found on the internet at reasonable prices. Board level modulators are also available. DVB-S is better as far as weak signal reception, multipath and motion than D-CATV but not DVB-T. DVB-S is more forgiving as far as amplifier linearity and IMD.

Gear made for WiFi can be used for ATV

if the transceivers are set for the Part 15 channels shared with the ham bands, or modified with firmware to move completely into the ham band. See the discussion of Broadband-Hamnet in the Digital Protocols and Modes chapter and www.AREDN.org which is primarily aimed at emergency communications. IP cameras can be plugged into Nano Stations, transmitted to a Hamnet node or receiver, and viewed on a computer screens.

Digital ATV signals using the USA broadcast DTV standard Eight-Vestigial Sideband (8-VSB) can also be received simply by using televisions made after 2008 in the same manner as analog cable televisions. Although modulator prices are coming down, the transmitters are expensive due in part to complexity and also to patent restrictions. 8-VSB is fine for fixed station to fixed station, but does not work for mobile even at slow speeds. A good comparison and description of 8-VSB and COFDM (Coded Orthogonal frequencydivision multiplexing) which is used by DVB-T, and C-DATV can be found at en.wikipedia.org/wiki/8VSB.

PICTURE QUALITY

Experimentally, using the US standard, FM ATV gives increasingly better pictureto-noise (snow) ratios than AM analog ATV at receiver input signals greater than 5 µV. That's also about the signal level for the 8-VSB DTV "cliff effect" where the signal disappears. The DTV all-or-nothing cliff effect occurs because the digital signal detector and processing in the receiver require a signal-to-noise ratio (SNR) of at least 15 dB for 8-VSB. Above 15 dB, you get an excellent picture, and at 14 dB SNR — nothing. Other DTV types — DVB-S or DVB-T — are a few dB better in the presence of noise depending on the bandwidth, mode and other factors.

Because of the wider noise bandwidth and FM threshold effect, AM analog video can be seen in the noise well before FM and DTV. For DX operation, it has been shown that AM

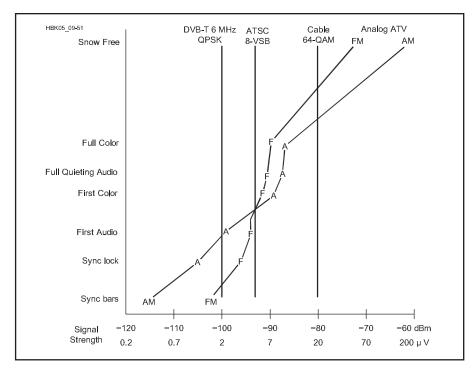

Figure 6 — Three approaches to ATV receiving. This chart compares AM, FM anddigital ATV as seen on a TV receiver and monitor. Except for DVB-T, signal levels are into the same downconverter with sufficient gain to be at the noise floor. The FM receiver bandwidth is 17 MHz, using the US standard. The three straight vertical lines for DTV illustrate the cliff effect described in the text.

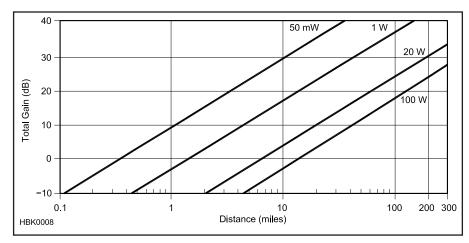

Figure 7 — This graph shows the possible line-of-sight distances for P5 (snow free) video reception for various analog AM ATV transmitter levels in the 70 cm band. Power levels shown are in PEP. The Total Gain is calculated by adding the antenna gain (dBd) for both the receive and transmit antennas and then subtracting the feed line loss (in dB) at both ends. For other bands: 33 cm, subtract 6 dB; 23 cm, subtract 9 dB; and 13 cm, subtract 15 dB. For FM ATV (4 MHz deviation, 5.5 MHz sound), add 12 dB. For DVB-T digital TV, the sudden loss of picture "cliff effect" distance is found by adding 39 dB. If the noise figure of the first stage in the downconverter is greater than 2 dB, subtract for each dB over 2. See the example in Table 1.

signals are recognizable in the snow at up to four times (12 dB) greater distance than FM, with all other factors equal. Above the FM threshold, however, FM rapidly overtakes AM. FM snow-free pictures occur above 50 $\mu V\!\!$, or four times farther away than with AM signals. The crossover point is near the

signal level where sound and color begin to appear for both systems. **Figure 6** compares analog AM, FM and digital ATV across a wide range of signal strengths.

DTV does not have the video resolution limitation of a 3.58 MHz color subcarrier as does NTSC AM and FM ATV. For DX or

Table 1 ATV DX Graph Example

Transmit antenna +10 dBd
Receive antenna +12 dBd
Transmit feed line -1 dB
Receive feed line -2 dB
6 dB noise figure -4 dB

Total Gain for 70 cm is 15 dB With 20 W PEP, range is 35 miles (Figure 7)

For 23 cm (–9 dB) gain is 6 dB With 1 W PEP, range is 3 miles (Figure 7)

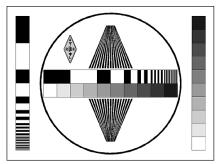

local ragchewing, resolution or snow free picture may not be a significant factor, but when using ATV for public service events, a crisp solid screen is a welcome benefit for coordinators. Video resolutions greater than NTSC 480i are possible with DTV running digital cameras and a modulation bandwidth of 6 MHz. 720p and 1080p are the most popular and picture aspect ratios are 4:3 or 16:9.

1.3 How Far Does ATV Go?

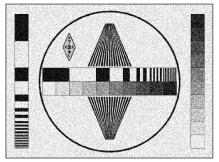

The theoretical snow-free line-of-sight distance for 20-W PEP 70 cm analog AM ATV, given 15.8-dBd gain antennas and 2 dB of feed line loss at both ends, is 150 miles. (See Figure 7.) In practice, direct line-ofsight ATV contacts seldom exceed 25 miles due to the curvature of the Earth with hills and buildings blocking the direct path. Longer distances are possible with over-the-RFhorizon tropo openings, reflections, or through high hilltop repeaters. A 2518-mile reception record is shown in Figure 2. (See the **Propagation of Radio Signals** chapter.) West Coast hams use the Hepburn Tropo Ducting Forecast at www.dxinfocentre. com/tropo_wam.html for openings, especially in the summer months to know when best to listen for the Hawaii beacons. The best initial indication that you have a path to a local ATVer or ATV repeater is how strongly you receive their 2 meter FM voice signal. There are internet web sites that can give you RF coverage maps such as Radio Mobile www.ve2dbe.com/rmonline.html and CRC-COVWEB at Irccov.ca/main. Some ATV repeater web sites have a coverage map you can check to see what the expected signal strength is for your QTH — see www.atn-tv. org/maps.htm.

The antenna system is the most important part of an ATV system because it affects both receive and transmit signal strength. For best DX, use low-loss feed line and a broadband high-gain antenna, up as high as possible.

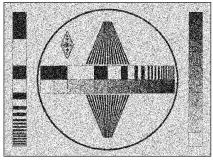

A snow-free, or "P5," picture rating (see **Figure 8**) requires at least $200 \,\mu\text{V}$ (-61 dBm) of signal at the input of the analog AM ATV

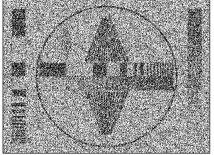

P5 — Excellent

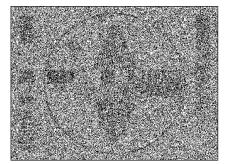

P4 — Good

P3 — Fair

P2 — Poor

P1 — Barely perceptible Figure 8 — An ATV quality reporting system.

receiver, depending on the system noise figure and bandwidth. The noise floor increases with bandwidth. Once the receiver system gain and noise figure reaches this floor, no additional gain will increase sensitivity. At 3-MHz bandwidth the noise floor is 0.8 µV (-109 dBm) at standard temperature in a perfect receiver. Analog TV luminance bandwidth rolls off around 3 MHz to separate it from the color subcarrier at 3.58 MHz. If you compare this 3 MHz bandwidth to an FM voice receiver with 15 kHz bandwidth, there is a 23 dB difference in the noise floor.

Much like the ear of an experienced SSB or CW operator, however, the eye can pick out sync bars in the noise below the noise floor. Sync lock and large, well contrasted objects or lettering can be seen between 1 and 2 μV with AM ATV. Color and subcarrier sound come out of the noise between 2 and 8 μV depending on their injection level at the transmitter and characteristics of your TV set. For the ATV DXer, using an older analog TV that does not go to blue screen or go blank (like a video squelch) with weak signals is a must, especially when rotating the antenna for best signal.

With DTV you get a perfect picture if the signal strength is above the cliff, and nothing or freeze-frame, if below. In multipath conditions the DVB-T transmitting station can try increasing the FEC and reducing the guard interval fractions as well as reducing the data rate to get a good enough picture with only a non-moving call sign in the picture. It can be more difficult and time consuming to swing the beam looking for a DTV signal because it can take as much as 10 seconds depending on the DTV mode set up for the receiver to lock on and decode the video. It is best to rotate the antenna in small increments, generally the 3 dB beam width of the beam, wait, and keep trying until found. Then split the difference of the beam headings from where the picture freezes or disappears.

Operators must take turns transmitting on the few available channels. Two meter FM is used to coordinate ATV contacts and the 2 meter link allows full-duplex audio communication between many receiving stations and the ATV transmitting station speaking on the sound subcarrier. This is great for interactive show and tell. It is also much easier to monitor a squelched 2 meter channel using an omnidirectional antenna rather than searching out each station by rotating a beam. Depending on the third-harmonic relationship to the video on 70 cm, 144.34 MHz and 146.43 MHz (simplex) are the most popular frequencies. The 2 meter audio is often mixed with the subcarrier sound on ATV repeater outputs so all can hear the talkback. If running DTV, you do have to have patience and get used to the delay or latency, which can vary from tenths of a second to 10 seconds depending on the mode, bandwidth and other factors. It takes time for the digital encoders and decoders to lock on and process the video data.

2 Amateur TV Systems

Regardless of the type of ATV you're interested in—analog AM, FM or digital—you'll need to assemble the appropriate receiving and transmitting equipment and find other stations to work. A basic AM 70 cm ATV station is shown in **Figure 9**. Very few multimode transmitters and transceivers support the broadband ATV mode and therefore most use equipment specifically designed for ATV. Sending video is easy by plugging in to the ATV transmitter your camcorder, video camera, digital camera, VCR, DVR, or any device with standard video output (usually RS-170 or CVBS) that can be viewed on an analog video monitor, VCR or a TV set's video input.

2.1 Analog AM ATV

Figure 10 shows the makeup of an analog AM TV channel (also called an NTSC channel) used for ATV, cable TV and for broadcast TV before the switch to digital. The channel is 6 MHz wide to accommodate the composite video, 3.58 MHz color subcarrier and 4.5 MHz sound subcarrier. Given the NTSC

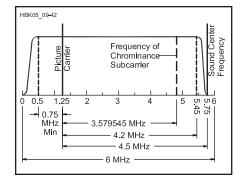

Figure 10 — An analog VSB NTSC 6 MHz video channel with the video carrier 1.25 MHz up from the lower edge. The color subcarrier is at 3.58 MHz and the sound subcarrier at 4.5 MHz above the video carrier.

525 horizontal line and 30 frames per second scan rates, the resulting horizontal resolution bandwidth is 80 lines per MHz. Therefore, with the typical TV set's 3-dB rolloff at 3 MHz (primarily in the IF filter), up to 240

vertical black lines can be seen. The horizontal scan lines are interlaced and this old NTSC standard is often noted as 480i/30. Newer TVs have better filters resulting in higher resolutions. Color bandwidth in a TV set is less than this, resulting in up to 100 color lines. Lines of resolution are often confused with the number of horizontal scan lines per frame. The video quality should be every bit as good as on a home video recorder. DXers, however, may add a 1 MHz or less band-pass filter between the downconverter and TV input on channel 3 to reduce the noise floor to dig out sync bars or black call letters.

Most ATV is analog AM double sideband (DSB), with the widest component being the sound subcarrier out ±4.5 MHz. As can be seen in **Figure 11**, the video power density is down more than 30 dB at frequencies greater than 1 MHz from the carrier — more than 90% of the spectrum power is in the first 1 MHz on both sides of the carrier.

To fit within a 6 MHz wide channel, NTSC broadcast stations used an approach called vestigial sideband (VSB). VSB involves sup-

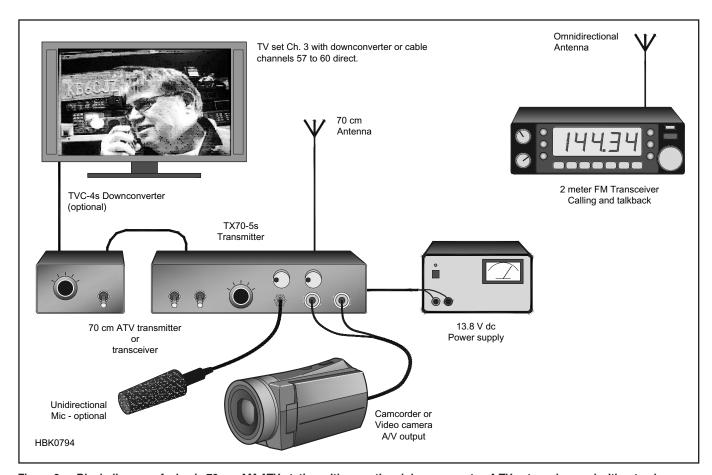

Figure 9 — Block diagram of a basic 70 cm AM ATV station with an optional downconverter. A TV set can be used without a downconverter, but it's better to have one for weak signal DX and if the video carrier frequency is more than 1 MHz from the cable channel frequency. If receiving an AM or DTV crossband repeater output on 33 or 23 cm, the downconverter would be connected to its own antenna and not through the TR relay in the transmitter. This makes it possible to see your own video coming back.

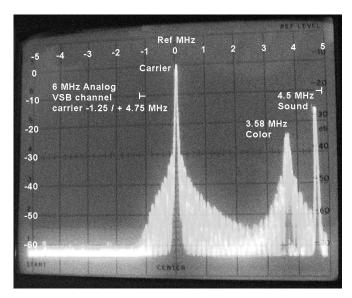

Figure 11 — Spectral display of a color analog AM VSB ATV signal. Spectrum power density varies with picture content, but typically 90% of the sideband power is within the first 1 MHz.

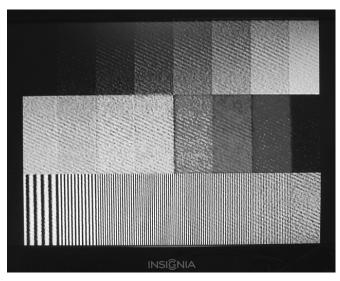

Figure 12 — AM ATV interference susceptibility. Notice the crosshatch lines from an interfering -100 dBm carrier 1 MHz above the -60 dBm video carrier frequency into the TV receiver.

pression, but not elimination, of the lower sideband so that it occupies less than 1 MHz. In addition, instead of modulating a 4.5 MHz subcarrier to produce sound, broadcast stations used a second sound transmitter offset above the video carrier by 4.5 MHz so that the sound signal does not appear in the lower sideband.

DSB and VSB are both compatible with analog cable TV tuners, but the lower sound and color subcarriers are rejected in the TV set IF filter as unnecessary. In the case of VSB, less than 5% of the lower sideband energy is attenuated. The other significant energy frequencies are the sound (set in the ATV transmitter at 15 dB below the peak sync) and the color at 3.58 MHz (greater than 22 dB down).

AM ATV FREQUENCIES

The lowest frequency amateur band wide enough to support an analog AM ATV channel is 70 cm (420-450 MHz), and it is the most popular. With transmit power, antenna gains and feed line losses equal, decreasing frequency increases communication range. The 33 cm (902-928 MHz) band generally covers half the distance that 70 cm does, but this can be made up to some extent with highgain antennas, which are physically smaller at the higher frequency. Depending on local band plan options, there is room for no more than two simultaneous AM ATV channels in the 33 cm and 70 cm bands without potential interference. Similar to over-the-air broadcast TV, adjacent channels are skipped to avoid interference from a stronger station immediately adjacent to a weaker one. Cable channels don't have that problem because

they equalize the amplitude of all the channels. If there is an in-band ATV repeater, simplex ATV operation shares space with the repeater input. Before transmitting, check with local ATV operators, repeater owners and frequency coordinators listed in the ARRL Repeater Directory for the coordinated frequencies used in your area.

The most popular in-band repeater output frequency is 421.25 MHz and is the same as cable channel 57. At least 12 MHz of separation is necessary for in-band repeaters because of TV-set adjacent-channel rejection and VSB filter characteristics. Cross-band ATV repeaters free up a channel on 70 cm for simplex and make it easier for repeater users to monitor their own repeated video with only proper antenna separation needed to prevent receiver desensitization.

Simplex, public service and R/C models use 426.25 MHz in areas with cross-band repeaters, or as an alternative to the main ATV activities on 434.0 or 439.25 MHz. The spectrum power density is so low at frequencies greater than 1 MHz from the video carrier of an AM analog ATV transmission that interference potential to other modes is low

On the other hand, interference potential to ATV from other modes is high. Because a TV set receives a 6-MHz bandwidth, analog AM ATV is more susceptible to interference from many other sources than are narrower bandwidth modes. Interference 40 dB below the desired signal can be seen in video in Figure 12. Many of our UHF (and higher) amateur bands are shared with radar and other government radio positioning services. Signals from these services show up as horizontal bars or popping in the picture. Interference from amateurs who are unaware of the presence of the ATV signal (or in the absence of a technically sound and publicized local band plan) can wipe out the sound or color, or can create diagonal lines in the picture

Other stations operating on narrowband modes more than 1 MHz above or below the video carrier rarely experience interference from an AM ATV signal, or even know that the ATV transmitter is on the air, unless the narrowband station is operating on one of the subcarrier frequencies or the stations are too near one another.

If the band is full and the lower sideband color and sound subcarrier frequencies need to be used by a dedicated link or repeater, a VSB filter in the antenna line can attenuate them another 20 to 30 dB, or the opposite antenna polarization can be used for more efficient packing of the spectrum.

Since the level of intermodulation distortion (IMD) found in most amateur linear amplifiers reinserts the lower sideband to within 10-20 dB of DSB, a VSB filter in the antenna line is a sure and cost-effective way to reduce the unnecessary lower sideband subcarrier energy if more than 1 W is used. VSB cable modulators can also be used if strict attention is made to keep the drive level in the proper range of highly linear amplifiers. In the more populated areas, 2 meter calling or coordination frequencies are often used to work out operating time shifts or other techniques to accommodate all users sharing or overlapping the same segment of the band.

RECEIVING AM ATV

Since the 70 cm band corresponds to cable

TV channels 57 through 61, seeing your first ATV picture may be as simple as connecting a good outside 70 cm antenna (aligned for the customary local polarization) to a cableready TV set's antenna input jack. Your broadcast TV antenna, twin-lead or RG-6 coax may not be good enough for receiving the much lower power ATV transmissions. Cable channel 57 is 421.25 MHz, and each channel is progressively 6 MHz higher. (Note that analog cable channels and the old NTSC broadcast UHF channel frequencies are different above channel 13.) Check the ARRL Repeater Directory for a local ATV repeater output that falls on one of these cable channels. Cable-ready TVs may not be as sensitive as a low-noise downconverter designed just for ATV, but this low cost technique is well worth a try. A higher gain antenna and/or low noise antenna preamp, preferably at the antenna, can be added later if the picture has snow in it.

Many newer TVs have to scan which channels and mode are active to retain in tuner memory. If your cable provider is running NTSC and channels 57 through 60 are active, then you are set to go. If not, then hopefully there is a nearby ATVer with a strong enough signal you can receive when you do the channel memory scan or who is willing to come over and transmit into a dummy load as a signal source.

Most stations use a variable tuned or crystal referenced downconverter specifically designed to convert the whole amateur band down to a VHF TV channel. Generally the 420 and 902 MHz bands are converted to TV channel 3 or 4, whichever is not used for over-the-air broadcast TV in the area. For 1240 MHz converters, channels 7 through 10 are used to get more mixer image rejection.

The downconverter consists of a low-noise preamp, mixer and tunable or crystal-referenced local oscillator. Any RF at the input comes out at the lower frequencies. All signal processing of the AM video and FM sound is done in the TV set. A complete receiver with video and audio output would require all of the TV set's circuitry except the sweep and video display components. There is no picture quality gain by going directly from a receiver to a video monitor (as compared with a TV set) because IF and detector bandwidth are still the limiting factors. The Automatic Frequency Control (AFC) in a TV will normally lock on to a video carrier over a little more than ±1 MHz, so frequency drift and accuracy are not nearly as significant as experienced with voice modes. For instance, a TV set to cable channel 59 (433.25 MHz) will normally lock on to a 434.0 MHz ATV signal.

A good low-noise amateur downconverter with 15 dB gain ahead of a TV set will give sensitivity close to the noise floor. A preamp located in the shack will not significantly

increase sensitivity, but rather may reduce dynamic range and increase the probability of intermodulation interference. Sensitivity can best be increased by reducing feed line loss or increasing antenna gain. Or you can add an antenna-mounted preamp, which will eliminate the effects of loss in the feed line and loss through TR relays in the transmit linear amplifier. Each 6 dB total improvement — usually a combination of increased transmitter power, antenna gain or receiver sensitivity and reduced feed line loss — can double the line-of-sight distance or improve quality by 1 P unit (a measure of picture quality).

DRIVING AMPLIFIERS WITH AM ATV

Linear amplifiers for use with wideband AM video require some special design considerations compared to amplifiers used for FM and SSB voice operation. Many high-power amateur amplifiers would oscillate (and possibly self destruct) from high gain at low frequencies if feedback networks and power RF chokes did not protect them. These same stability techniques can affect operation over a 5-MHz video bandwidth. Sync, color and sound can be distorted unless the amplifier has been carefully designed for both stability and AM video modulation.

A few manufacturers offer special ATV amplifiers or standard models designed for all modes, including ATV. The collector and base bias supplies have a range of capacitors to keep the voltage constant under video modulation, while at the same time using the minimum-value low-resistance series inductors or chokes to prevent self-oscillation. Amplifiers using LDMOS devices have better linearity and lower IMD characteristics which are desirable for ATV.

Almost all amateur linear power amplifiers exhibit some degree of gain compression from half-power to their full rated PEP output. For proper AM ATV operation, the amplifier can be driven to PEP output power of no more than its 1 dB gain compression level. If more

power is needed, the analog AM ATV exciter/modulator can use a sync stretcher to maintain the proper transmitted video-to-sync ratio to compensate for higher outputs (see **Figure 13**)

To adjust a station with an ATV amplifier, disconnect the video source and set the pedestal control in the ATV transmitter's modulator for maximum power output. Then set the transmitter's RF power control to drive the amplifier to 90% of rated PEP output (this is the peak sync level). The 90% level is necessary to give some headroom for the 4.5 MHz sound subcarrier that is mixed and added with the video waveform. Once this peak sync level is set, use the blanking pedestal control to reduce amplifier output to 60% of this level. For example, a 100-W amplifier would first be set for 90 W with the RF power control and then 54 W with the pedestal control. Then the video can be plugged back in and the video gain adjusted for best picture.

If you could measure RF output with a peak-reading power meter made for video, the power would be between 90 and 100 W PEP. A dc oscilloscope connected to an RF diode detector in the antenna line shows that the sync and blanking pedestal power levels remain constant at their set levels regardless of video gain setting or average picture contrast. On an averaging power meter, however, it is normal with video to read about half the amplifier's rated power. The power reading will actually decrease with increasing video gain or with a change to a predominantly white picture. An averaging RF power meter cannot give an accurate measurement for an AM video signal given so many variables. If the amplifier drive level is properly set up according to the procedure outlined above, the actual sync tip PEP will remain constant.

Analog cable TV modulators can also be used to drive linear amplifiers, but most do not have adjustable sync stretchers. When driving an amplifier, the level must be kept below the upper nonlinear gain curve of the

Figure 13 — An oscilloscope used to observe a video waveform. The lower trace is the video signal as it comes out of the sync stretcher. The upper trace is the detected RF signal from the amplifier.

amp's output curve in order to maintain the proper video to sync ratio. The same is required when driving an amp from any low power ATV transmitter that does not have adjustable sync stretching. Most amateur amplifiers can be driven to their 1 dB gain compression output levels for ATV, which typically occurs around half the rated PEP output.

2.2 Frequency Modulated ATV

In Europe, FM ATV on the 23 cm (1240 MHz) band is the standard because there is little room for ATV in the amateur 70 cm band. In the US, AM on 70 cm remains the most popular ATV mode because of equipment availability, lower cost, less occupied bandwidth and use of a standard analog TV set for receiving. However, FM ATV is often used by repeater owners for links and alternate inputs.

As shown in **Figure 14**, FM ATV occupies 17 to 21 MHz depending on deviation and sound subcarrier frequency. While the 70 cm band is 30 MHz wide and thus theoretically could accommodate a 20 MHz wide FM ATV signal, the great interference potential to other users of the band precludes its use there. Most available FM ATV equipment is made for the 0.9, 1.2, 2.4 and 10.25-GHz bands. The 3.3 and 5.6 GHz amateur bands are also being explored by using C-band satellite receivers and converted Part 15 equipment.

The US standard for FM ATV is 4 MHz deviation with the 5.5-MHz sound subcarrier set to 15 dB below the video level. Suggested frequencies are 1252 or 1255 MHz to stay away from FM voice repeaters and other users

higher in the band, while keeping sidebands above the 1240 MHz band edge. Using the US standard, with Carson's rule for FM occupied bandwidth (see the **Modulation** chapter), it comes out to just under 20 MHz — so 1250 MHz would be the lowest possible frequency. Check with local frequency coordinators before transmitting because the band plan permits other modes in that segment that may not be published.

C-band satellite TV receivers directly tune anywhere from 900 to 2150 MHz and may need a preamp added at the antenna for use on the 33 cm and 23 cm amateur bands. Early satellite TV receivers were made for antenna mounted LNBs (low noise block converters) with 40 dB or more gain. Satellite receivers are made for wider deviation (11 MHz) and need some video gain to give the standard 1-V P-P video output when receiving a signal with standard 4-MHz deviation. The additional video gain can often be had by adjusting an internal control or changing the gain with a resistor.

Some of the inexpensive Part 15 wireless video receivers in the 33 cm band use 4-MHz deviation FM video. Most of the 2.4-GHz Part 15 units are FM, so they can be used directly. On 2.4 GHz, some of the Part 15 frequencies are outside the ham band and care should be taken to use only those frequencies at least 8 MHz inside the 2390-2450 MHz ham band.

Part 15 receivers may or may not have the standard CCIR 405-1 de-emphasis video network, however, so some circuitry may have to be added. Video pre-emphasis in the transmitter and de-emphasis in the receiver can double the communication distance or give 6 dB of SNR improvement by reducing the

receiver noise bandwidth. Coordination among local stations is needed, though, because you cannot match stations that have the networks with those that don't without distorting the video greatly. The sound subcarrier might also be on 4.5, 5.8, 6.0, 6.2, 6.5 or 6.8 MHz rather than 5.5 MHz. The FM sound deviation is 50 kHz.

2.3 Digital ATV

The greatest advantage to running digital ATV is that you have a perfect P5 picture all the way down to 15 dB (with 8-VSB) above the noise floor, and higher definition or more than one picture are possible in the same 6 MHz channel width used for analog AM ATV (see Figure 15). If you use the 40 dB signal-to-noise level at -61 dBm required to have snow-free ATV as a reference, DVB-T is 27 dB better than the 4 MHz deviation FM ATV and 39 dB better than analog AM ATV. This is a significant consideration for longdistance, point-to-point, line-of-sight paths and for paths requiring wide fade margins. Tuning in DTV requires greater accuracy and takes more patience if using a tunable downconverter. D-CATV QAM, for instance, at cable channel 58 on one TV needed to be tuned within 400 kHz but took a second or two within that range for the picture to appear. 64-QAM is much more resistant to interference than AM and stays P5 up to almost equal amplitude with another carrier.

DTV can send much more usable picture and sound information in the same bandwidth as analog AM ATV under the theory that you don't have to send a continuous serial stream of a scanned picture at 30 interlaced frames per second. Rather, in DTV you send one

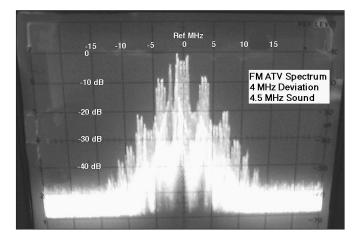

Figure 14 — Spectral display of an FM ATV transmission using 4 MHz deviation with a 4.5 MHz sound subcarrier. (Note that 5.5 MHz is the standard and would be 2 MHz wider.) Occupied bandwidth as defined in FCC Rule 97.3(a)(8) is –26 dB down from the mean power points.

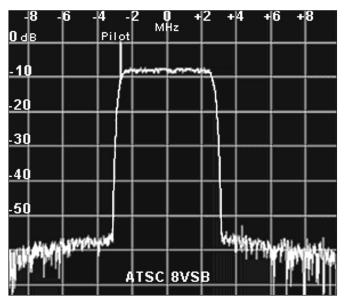

Figure 15 — Spectral display of an ATSC 8-VSB digital TV transmission. Note the pilot carrier unique to this mode of DTV.

whole frame and then send frames of only the changed pixels (or those pixels predicted to change, as explained in the next paragraph). Just the changes are sent a specified number of times (usually up to 15 times) before starting over again with a new complete frame.

There are complex algorithms based on how the human eye and mind perceive the picture as well as data compression techniques. For instance, there is the probability that a pixel or group of pixels that are moving in a direction on the screen will occupy the adjacent pixel location at a certain time. According to Henry Ruh, AA9XW (a longtime ATVer and retired Chief Engineer at WYIN-TV in Chicago), the coder/decoder (codec) software may expect a moving pool ball to continue in a straight line. If you watch closely, however, you may see the ball go deeper into the cushion than it really did until the next full frame. The bottom line is that the picture you see may be 10% actual data and 90% predictive algorithm for what your mind expects to happen.

DIGITAL ATV TRANSMITTER REQUIREMENTS

DTV transmitters start with a modulator typically putting out around a milliwatt or 0 dBm followed by a series of very linear amplifiers, each of which is driven well below their 1 dB gain compression and low third-order intermod intercept points. A DVB-T modulator is quite complex and usually must be programmed with a PC computer if you want to change the factory settings, center frequency and add your call letters in as the Service Name for ID purposes. There are so many parameters that can be selected, that

only programming from a computer is practical – hardly any knobs to adjust will be found. It is not unusual for the first ham on DATV in an area to program the modulator for each new ham coming on with the local frequency and parameters. The size of a DVB-T modulator can fool you given the level of today's IC miniaturization and software sophistication. Some are available as a USB dongle. **Figure 16** shows the spectral display of a 6 MHz DVB-T 8K QPSK signal.

Video input is typically an RCA phono jack or BNC for CVBS input. BNC may also be for analog high-definition cameras but most newer modulators use a HDMI jack for HD. DVRs and Adaptors for practically any camera video mode can be found to convert to HDMI. Modulators usually sense the type of video and automatically select the right parameters to encode.

DTV transmissions are rated at average power. With DVB-T modulation, the peak power is more than 6 dB greater than the average depending on the modulation parameters. DTV transmission requires an amplifier with high linearity and good IMD performance to prevent distortion, noise and spectrum sideband growth. For proper operation, amplifiers for DVB-T are generally run at 1/3 of its 1 dB gain compression level. For instance the KH6HTV video model 70-7B amplifier shown in Figure 4 is rated at 20 W FM or CW, 10 W AM ATV and 3 W DATV. These are rule of thumb levels with variations between devices. Lower transmit power levels are not as significant of a consideration with DVB-T as it would seem. As described earlier, DTV requires less signal strength than analog AM ATV to produce a P5 picture. Bipolar amps are rarely used, with the preference going to the power FET type of devices, such as LDMOS, with their better linearity and low IMD. Unless you have a spectrum analyzer to verify your amplifiers suitability and set up, it is best to stay with proven amplifiers for DATV. Since modulators take some time to load the firmware on power up, hams usually leave them on and switch the amplifier and antenna T/R relay on and off for transmit/receive. The amplifiers then need good input-to-output isolation when switched to off or standby in the receive state.

As can be seen in Figure 15, in an 8-VSB signal there is a pilot carrier 310 kHz up from the lower channel edge generated by a dc offset of the eight-level modulation. The pilot carrier has a tight tolerance of 3 Hz and gives the RF PLL circuits in the 8-VSB receivers something to lock onto that is independent of the data being transmitted. Unlike 8-VSB and DVB-T, DVB-S or D-CATV do not have a pilot carrier and requires less amplifier headroom (compare **Figure 17** to Figures 15 and 16).

With DTV, it's not good amateur practice to follow the ham tradition on other modes of increasing amplifier drive to the point that a receiver starts to break up and then back the drive down a little. Although increased transmitter IMD may not affect the received signal until the combination of the received signal-to-noise and the added transmitter amplifier noise reaches the cliff and the picture goes away, the generated sideband levels can be quite large and interfere with other users on adjacent frequencies.

An analog VSB 6 MHz bandpass filter in the antenna line can help keep the unwanted

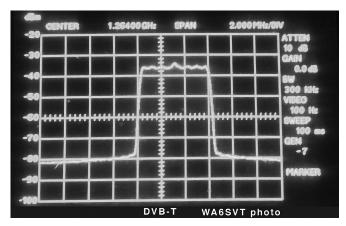

Figure 16 — Spectral display of a 6 MHz DVB-T 8K QPSK signal from the modulator used at the WA6SVT repeater. The "Haystacks" of DVB-T, DVB-S and cable 64-QAM are similar, but DVB-T has a center pilot carrier that can be seen. While not apparent, the peak to average power difference can be as much as 15 dB. This 8K QPSK DVB-T signal actually has 6817 carriers spaced 837 Hz apart.

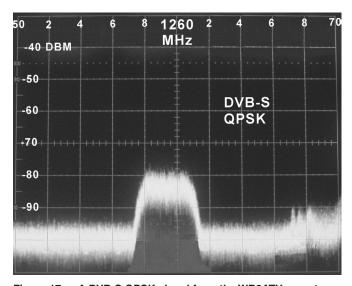

Figure 17 — A DVB-S QPSK signal from the WR8ATV repeater output as received on a spectrum analyzer. Note that the average power appears to be not too far above the noise floor, but gives a P5 picture. P units are measures of picture quality from P1 to P5 with P5 being the clearest and best picture.

Figure 18 — Mobile ATV as shown here with a portable TV works fine using D-CATV 64-QAM, but it exhibits occasional freeze or tile effect from drop outs and multipath.

Figure 19 — Art Towslee, WA8RMC, in his shack transmitting QPSK DTV through the local ATV repeater in Columbus, Ohio.

sideband growth down. As can be seen in Figures 15, 16 and 17, DTV spectrum power density is high across the whole channel width and will show up as noise in a narrowband receiver tuned within the 6 MHz channel. For this reason, DTV running any significant power from an amplifier, should be used in the higher bands or 420-431 MHz segment of the 70 cm band so as not to interfere with FM voice repeaters, weak signal modes and satellite work. However, those areas that use AM video carriers of 434.0 or 439.25 might be able to use 2 MHz DVB-T centered at 434.0 and 439.0 to avoid significant energy in the satellite and FM voice repeater segments. Check your local band plan. Modulators need to be selected that will generate 2 MHz modulation and are harder to find. 6, 7 and 8 MHz are the norm.

DVB-T with 2, 4 or 6 MHz bandwidth can use the same channel as AM ATV, but the spectrum power density is relatively flat across the bandwidth and care must be taken with amplifiers to keep sideband growth down below 30 dB and within the channel. DTV frequency is specified as the center of the occupied bandwidth. For instance, the channel for an AM ATV carrier at 421.25 would go from 420.0 to 426.0 MHz. A DVB-T transmission running 6 MHz bandwidth in the same channel would be described as running at 423.0 MHz. The operating frequency is not generally shown on the front panel, but rather a channel number that is user programmed.

DTV ISSUES

Latency - The DVB-T digital processing takes time at both ends, which can vary with the type, bandwidth and other parameter modulator settings. The higher the desired picture resolution, the higher the required

bandwidth and results in longer latency. Delays can typically be anything from .5 to 5 seconds depending on the speed of the codec processors. System latency can be measured as shown in **Figure 20** by aiming the camera at a clock and snapping a photo with a digital camera of the clock and the system video monitor to get the difference in time. It takes some getting used to the wait for another station to respond back to you if running duplex ATV or talking back on 2 meters, especially if using a DTV in/out repeater where the latency will be double that

of simplex. It also takes time for the DVB-T receiver to sync up and lock on to the new signal after another station starts transmitting. These delays can vary from tenths of a second to many seconds. Power up delays can take as much as a half minute with modulators and 10 seconds for receivers. For this reason, both are typically left powered on, and only the linear amp and antenna relay are switched between transmit and receive. Linear amplifiers and T/R antenna relays totaling in the order of 100 dB isolation in receive must then be used to keep the modu-

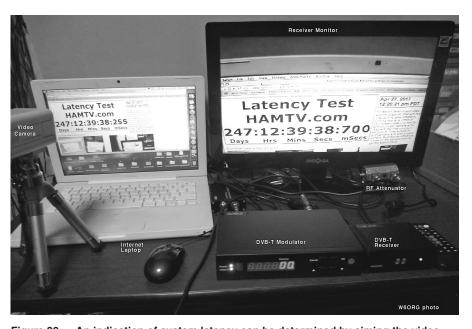

Figure 20 — An indication of system latency can be determined by aiming the video camera at a digital clock, in this case a count-down from the internet with milliseconds, and shooting a photo with a digital camera of both the clock and receive monitor to compare the times. Here, total delay through a DVB-T modulator and receiver running 2 MHz bandwidth with a CVBS 480i camera is about ½ second.

lator from interfering with the receiver.

Delays make it more difficult to aim and focus the cameras if monitoring your own video. Camcorders are preferred for DATV as they have a real time monitor built in and most current ones have the HDMI output for direct connection to monitors and DVB-T modulators

With Broadband-Hamnet, the latency will vary by the processing time of the computer and its application used to see the video, system loading, number of nodes and bandwidth. An experiment using the latency test outlined above showed even with a direct connection using an Ethernet crossover cable between an IP Camera and a computer, processing speed makes a big difference. A 2008 MacBook had a delay of 3.4 seconds and a 2014 Mac Mini only 0.4 seconds.

Controlling an R/C vehicle can be more challenging with DATV vs. AM or FM ATV because of latency. Weight and battery life is another factor.

Standardization - The cost, complexity and availability of gear to set up a DATV station has slowed the development of which way to go among the DTV modes until recently. DVB-T seems to have the most benefit for hams vs. the other DTV modes. It has the best distance and performs well with multipath and motion. Set top boxes for receiving DVB-T can be found on the internet for reasonable cost. However, these do not do 2 or 4 MHz bandwidth and do not tune the 70 cm ham band directly, requiring a downconverter. But there are a few sources of receivers and transmitters aimed for the ham radio market such as HI-DES (hides. com.tw) and KH6HTV VIDEO (kh6htv.

com). DATV-Express (datv-express.com) has an assembled board level exciter/transmitter with software. So far, they still require the user to program the modulator with a computer or scan an active channel into memory to receive. See Application Note AN-18B at kh6htv.com/application-notes on setting up the Hi-Des modulator and receiver. A local DATV Elmer or source willing to supply them ready to go set up on your local frequency can be a big factor in getting on DATV. DVB-T modulators send a Packet Identification number (PID) in its data transport stream that is used by stations to tell the receivers to recognize only their station or program on a channel. It is similar to CTCSS with FM voice. All hams in an area need to have the same video PID number – 641 is suggested.

The current recommended setup for DVB-T modulator ATV is:

Modulation: 6 MHz bandwidth, Constellation QPSK, FFT: 8K, FEC code rate: 7/8, Guard Interval: 1/16, Max Data bit rate: 5856 kbps, PMT PID: 640, Video PID: 641, Audio PID: 642, Network, Service and Provider Name: your call letters.

Video source: Camcorder with HDMI plug, 1080p resolution, H.264, 16:9 aspect ratio.

2.4 ATV Antennas

Foliage greatly attenuates signals at UHF, so place antennas above the treetops for the best results. Beams made for 432 MHz SSB/CW work or 440 MHz FM may not have enough SWR bandwidth to cover all the ATV frequencies for transmitting, but they are

okay for reception. A number of manufacturers make beam antennas designed for ATV use that cover the whole band from 420 to 450 MHz. Use low-loss feed line and weatherproof all outside connectors. Almost all ATV antennas use N connectors, which are more resistant to moisture contamination than other types. See the **Transmission Lines** and **Component Data and References** chapters for help with appropriate cable and connectors.

Antenna polarization varies from area to area. It is common to find that the polarization was determined by the first local ATV operators based on antennas they had in place for other modes. Generally, UHF/microwave operators active on SSB, CW and digital modes have horizontally polarized antennas, while those into FM, public service or repeaters have vertical antennas. Check with local ATV operators before permanently locking down the antenna clamps. Circularly polarized antennas let you work all modes, including satellites and have less multipath effects.

2.5 ATV Identification

ATV identification can be on video or the sound subcarrier. A large high-contrast callletter sign on the wall behind the operating table in view of the camera is the easiest way to fulfill the requirement and more easily recognized (see **Figure 21A**). Transmitting stations fishing for DX during band openings often make up call sign IDs using fat black letters on a white background to show up best in the snow. Their city and 2 meter monitoring frequency (typically 144.34 or 146.43 MHz) are included at the bottom of the sign

(B)

Figure 21 — At A, the simplest video identifier is to draw your call sign on a piece of paper and put it on the wall of your ham shack and in view of the camera. Doug Moon, K6KMN, also has his old auto call letter license plate as his ID. At B, the call sign, event name and location are overlaid on the video. During a public service event such as a long trail running race it is easy to forget to ID especially if operating full duplex and a lot is going on. See www.foothillflyers.org/hamtvac100.html for a description of ATV at the Angeles Crest 100 Mile Trail Race.

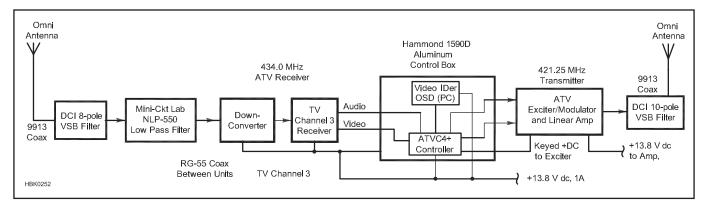

Figure 22 — A block diagram of a 70 cm in-band ATV repeater. The omnidirectional antennas are vertical and require 20 feet (minimum) of vertical separation to get >50 dB isolation to prevent receiver desensitization. Horizontal omnidirectional antennas require much more separation. A low-pass filter on the receiver is also necessary because VSB or cavity type filters repeat a pass-band at odd harmonics and the third-harmonic energy from the transmitter may not be attenuated enough. While AM ATV is shown, other modes and bands can be substituted. Video ID can be done with a video overlay board like the Intuitive Circuits model OSD-ID+ — by itself or even overlaid on a tower cam. The Intuitive Circuits ATVC-4+ ATV repeater controller board can do all the control box functions as well as remotely select from up to four video sources such as links.

to make beam alignment and contact confirmation easier. With DVB-T and Broadband-Hamnet video, the call can be programmed into the digital address header as the Service Name which is continuously sent.

Quite often the transmission time exceeds 10 minutes, especially when transmitting demonstrations, public service events, space shuttle video, balloon flights, or from a recording. Intuitive Circuits makes a variety of boards that will overlay text on any video looped through them. Call sign characters and other information can be programmed into the board's nonvolatile memory by onboard push buttons or an RS-232 interface from a computer (depending on the version

and model of the board). See Figure 21B. One model will accept NMEA-0183 standard data from a GPS receiver and overlay latitude, longitude, altitude, direction and speed, as well as call letters, on the applied camera video. This is ideal for ATV rockets, balloons and R/C vehicles. The overlaid ID can be selected to be on, off or flashed on for a few seconds every 10 minutes to automatically satisfy the FCC ID requirement. The Intuitive Circuits ATVR+ ATV repeater controller board has an automatic nine-minute timer, and it also has an end-of-transmission hang timer that switches to another video source for ID.

2.6 ATV Repeaters

There are two kinds of ATV repeaters: inband and cross-band. In-band repeaters for 70 cm are more difficult to build and use, yet they are more popular because equipment for that band is more available and less expensive. Some ATV repeaters have added streaming video of their outputs to the Internet so users can see when they are active. Some repeaters even use the Internet to establish links. A good number of US repeaters can be found on the www.batc.tv Streaming Members Web site and some accept check-ins during nets.

Why are 70 cm ATV repeaters more difficult to build than voice repeaters? The wide

Figure 23 — At left, an ATV repeater "tower cam" IDs have become popular so that users can see approaching weather. Some cameras have remote pan and tilt, so users can observe ice build-up on antennas or activity at the repeater site. At right, Roland KC6JPG. who loves playing with video overlays and graphics, conducts the Tuesday night net through the ATN (Amateur Television Network) hub repeater on Santiago Peak. Check-ins are on the air from eight linked repeaters in three states. Inputs vary using AM. FM and DVB-T. Grant, VK3XTV, who sometimes checks in from Melbourne Australia via the BATC streaming video on the Internet, was in the states visiting Mike, WA6SVT.

bandwidth of ATV makes for special filter requirements. Response across the 6-MHz passband must be as flat as possible with minimum insertion loss, but response must sharply roll off to reject other users as close as 12 MHz away. Special 6 to 10 pole interdigital or combline VSB filters are used to meet the requirement. An ATV duplexer can be used to feed one broadband omnidirectional antenna, but an additional VSB filter is needed in the transmitter line for sufficient attenuation to keep noise and IMD product energy from de-sensing the receiver. The receiver and possibly the transmitter might also need a low-pass filter to attenuate the third harmonic which can pass through a VSB or band-pass filter with little attenuation and overload the receiver front end.

A cross-band repeater requires less sophisticated filtering to isolate the transmitter and receiver because of the great frequency separation between the input and output. No duplexer is needed, only sufficient antenna

spacing or low pass and/or high pass filters. In addition, a cross-band repeater makes it easier for users to see their own video. Repeater linking is easier too, if the repeater outputs alternate between the 23 cm and 33 cm bands. Wide-area linking has been done using the 2.4, 3.4 and 5.6 GHz bands using modified Part 15 FM transmitters with amplifiers or streaming video from the internet. Six ATV repeaters in Southern California are linked to one in Las Vegas NV and another in Mesa AZ (See **Figure 23A**).

A 70 CM ATV REPEATER

Figure 22 shows a block diagram for a simple 70 cm in-band analog AM ATV repeater. No duplexer is shown because the antenna separation (>50 dB) and VSB filters provide adequate isolation.

To prevent unwanted key up from other signal sources, ATV repeaters use a video operated relay (VOR) in the controller. The

VOR senses the horizontal sync at 15,734 Hz in much the same manner that FM repeaters use CTCSS tones. Just as in voice repeaters, an ID timer monitors VOR activity and starts the repeater video ID generator every nine minutes, or a few seconds after a user stops transmitting. A tower-mounted camera is often used in place of a video ID generator at repeaters (see Figure 23B).

The repeater transmitter power supply should be separate from the supply for the rest of the equipment. With AM ATV the current varies greatly from maximum at the sync tip to minimum during white portions of the picture. Power supplies are not generally made to hold tight regulation with such great current changes at rates up to several megahertz. Even the power supply leads become significant inductors at video frequencies. They will develop a voltage across them that can be transferred to other modules on the same power supply line.

3 ATV Applications

3.1 Public Service

Live video from an incident site back to an Emergency Operations Center (EOC) is a valuable addition to disaster communications. A real-time view of the incident scene can give commanders an immediate feel for the overall picture of what is going on or zoom in on a critical component rather than rely solely on descriptions relayed by voice or data. While ATV has cut down the voice traffic repeats and clarifications, it has the added benefit of full duplex audio. The ATV transmitting station in the field talks on the sound subcarrier and the EOC can talk back at the same time on 2 meter FM voice. Races. parades and other public service events benefit from a ham volunteer transmitting video back to medical and emergency response personnel of what is happening at a critical street corner or incident as shown in Figure **24**. See how to put together a portable ATV transmitter in a belt pouch at www.hamtv. com/atvpouch.html and on page 1.70 of the 11th edition of the ARRL Operating Manual for radio amateurs. A camera and transmitter can be mounted on a robot and sent into a hazardous situation with no risk to people. The BCARES AREC group in Colorado has put together a high definition DVB-T transmitter system in a backpack for emergency communications and public service events - See the referenced article by Jim Andrews, KH6HTV. Broadband-Hamnet is being developed and installed with nodes at high locations to serve the emergency communications needs of an area. Besides voice and data

they can stream video similar to SKYPE but using the ham bands.

AN ATV "GO KIT"

Communications "Go-Kits" are popular with ARES and RACES groups. When an

emergency occurs, hams can just grab their kit and go out in the field with everything they need. Nick Klos, AC6Y, put together three ATV Go-Kits for the police department ARES group in Corona, California. See Figure 25. Each kit uses an easy-to-transport

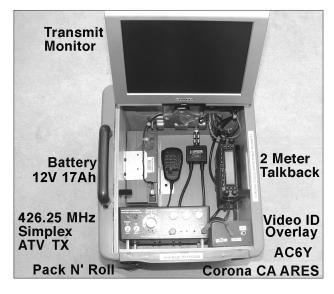

Figure 24 — A low power 50 mW battery operated portable 70 cm AM ATV transmitter is ideal for short range line of sight paths of up to 2 miles using 5 element beams. This setup can be used to show a critical intersection or condition of runners as an early warning to emergency response and aid station volunteers at races.

Figure 25 — This portable ATV Go-Kit for emergency and public service work was built by Nick Klos, AC6Y. It includes a 70 cm ATV transmitter, 2 meter FM transceiver and battery in a Pack N' Roll container.

Pack-N-Roll enclosure. (Pack-N-Rolls come in various sizes, have wheels, and have an extendable handle similar to airline carry-on luggage.) The ATV transmitter, 2 meter

transceiver, battery and optional video monitor are fastened to plywood cut to fit the inside of the enclosure. A dc power supply can also be added if ac is available, or power can come from a dc extension cord with clips to connect to a car battery.

If the distance to be covered is short enough, a 2 meter/70 cm dual-band mobile vertical antenna connected through a duplexer and mounted on at least 10 ft of TV mast above the Go-Kit is sufficient for communication with a mobile command post. Longer or obstructed paths between the incident site

and the EOC may require beams and more antenna placement care.

Multiple ATV Go-Kits allow for views of an incident site from different perspectives, including the police department helicopter and mobile or portable stations on the ground. The Go-Kits can also be used for parades, running and bike races, which are good operational practice for when the real emergency might happen.

PORTABLE REPEATERS

A portable ATV repeater for public service

events can also be built in a Pack-N-Roll enclosure or a milk crate for easy transport and set up on the top of a building or hilltop by car or even helicopter. The path between an ATV station in the field and the EOC is rarely line-of-sight, so the portable ATV repeater can be placed at a high point that can be accessed from both locations.

The portable repeater shown in Figure 26 is a cross-band unit with 70 cm input and 23 cm output. By using 70 cm input to the repeater, you get the best distance for the lowest power by those moving around an incident site with hard-hat cameras or portable units. Another advantage to using lowin and high-out at the repeater is that filtering is much easier because you don't have to contend with strong repeater transmitter harmonics in the receiver. Antenna separation of 5 ft is usually enough running a less than 5-W, low-in/high-out portable repeater.

With weaker signals, a low-pass filter in the 70 cm receiver feed line and a high-pass filter in the 23 cm transmitter feed line may help to minimize desense. If a portable ATV repeater system is used at or near a communications site, band-pass filters in the antenna feed lines should be used to prevent intermodulation interference or receiver overload from nearby transmitters.

With compact 10-dBd gain corner reflectors or higher gain beams on 23 cm, you can get more than 5 miles line-of-sight from the repeater to the EOC with just 3 W of transmit-

Figure 26 — At A, Tom O'Hara, W6ORG, adjusts a portable ATV repeater for public service work that can be built in a milk crate. The block diagram is similar to Figure 14 but without the VSB filters. The transmitter is a PC Electronics RTX23-3 on 1253.25 MHz, the receiver is on 426.25 MHz, and small beams or omni antennas are used. For more details on construction, visit www.hamtv.com/info.html#portrpt. At B, the repeater is flown to a hilltop and quickly set up. Sharon Kelly, KF6OQO, is adjusting the antenna. At C, the video of a fire can be seen at an EOC on the other side of the hill while Gary Heston, W6KVC, talks back to the incident site ATV operator on 2 meters.

ter power. The portable repeater shown is self-contained with a 12-V, 17-Ah battery that will last about 12 hours. Alternatives include ac-operated 13.8 V, 3 A power supply or a dc cord clipped to a car battery. A local camera can be plugged in and used if needed. Details of the milk crate repeater can be found

at www.hamtv.com/info.html under Portable Public Service Repeater.

3.2 Radio Control Vehicles

Some hams also enjoy operating radio control (R/C) vehicles, and ATV can add a new dimension to that hobby. The size,

> weight and cost of color cameras have come way down, and ATV transmitters are smaller as well, so ATV stations can more easily be integrated into R/C vehicles to give them eyes and in some cases ears. Quadcopters and drones with video have become popular and some are on shared Part 15 frequencies in the higher ham

AN EDUCATIONAL TOOL

Mark Spencer, WA8SME (ARRL Amateur Radio Education and Technology Coordinator) added ATV capability to a Parallax Board of Education Robot (BOE/ BOT) as shown in **Figure 27**. With the add-on ATV board. the BOE/BOT simulates a Mars Lander. The robot and ATV board are also used to teach students how a TV remote control works, as well as demonstrate remote sensing and data linking. This ATV application has encouraged students to use the kit as a science class project and

become licensed hams in the process.

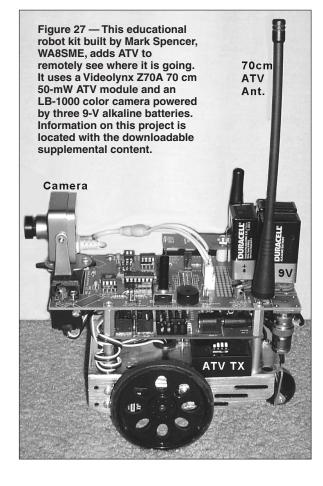

R/C VEHICLE TIPS

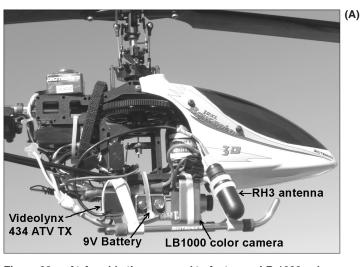

ATV and data transmitter modules have been put in R/C aircraft, blimps, cars and boats. A Videolynx 434 50 mW transmitter on 70 cm is enough to give good video for ½ mile or so around an R/C flying field. An inverted ground-plane or vertical dipole is used typically on aircraft, but nulls in the radiation pattern can show up at steep bank angles. Ground-plane antennas are also used for receive because the pattern is broad. Mounting the receive antenna at least 10 ft above ground can help avoid multipath ghosting or signal blockage from nearby people and vehicles. Use of higher gain omnidirectional antennas is tempting for greater distance, but they have narrower radiation patterns and more nulls.

Operation at higher frequencies requires shorter antenna lengths that might better fit the physical size limitations of an R/C vehicle, but snow-free distance will be shorter given the same transmitter power and receive antenna gains.

If ac power is not available at the flying field for plugging in a TV, look for a portable television that can be powered from batteries. Some hams have used TV tuners designed for use with laptop computers. Position the screen to be north facing for least sun washout. It is best for even experienced R/C operators to not fly solely by video, but to have a copilot observe directly as the camera's field of view is limited.

Typical 72 MHz or 50 MHz R/C receivers are not designed to operate with a transmitter in the same vehicle. The R/C receiver front end could overload from ATV transmitter RF. so control distance testing is a must before

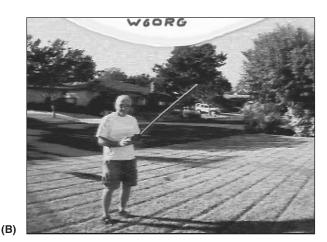

Figure 28 — At A, cable ties are used to fasten an LB-1000 color camera, Videolynx 434 ATV transmitter, 9 V battery and Diamond RH3 antenna to an R/C helicopter powered by an electric motor. At B, a computer with a TV tuner plugged into the USB port is used to view video coming from the ATV transmitter on the R/C helicopter — in this case, looking back at the R/C model operator.

the first flight. Testing can be done by having another ham (with a handheld radio for talkback) carry the R/C vehicle out to the normal limit of control distance. Then turn on the R/C transmitter and verify that the controls are working normally. Finally, turn on the ATV transmitter and again verify operation.

If the R/C receiver is captured by the ATV transmitter, then experiment with lowering power, changing antenna placement, or adding shielding or filtering. In the past, crystal oscillator leakage was often the culprit, rather than the 70 cm output, and could be cured by Shielding. Interference may be less of a problem with a newer ATV transmitter that uses a PLL oscillator.

A PRACTICAL EXAMPLE

The added weight of the ATV system on the electric R/C helicopter shown in Figure 28 is only 7 oz, but first you need to determine that the craft can lift the added load. The extra equipment must be mounted to maintain balance around the aircraft's center of gravity. Some testing with equivalent weights first can save equipment from possible damage. Note the stubby flexible antenna mounted upside down on one of the skid supports. This is counterbalanced by mounting the R/C receiving antenna on the opposite side.

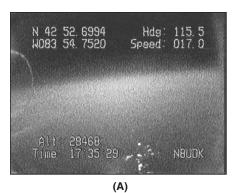

A separate battery should be used for the ATV system rather than tapping into the motor or R/C receiver battery. The voltage will vary during the flight and could put motor noise in the video. A standard 9 V alkaline battery will last almost two hours continuous duty with this system.

On larger R/C aircraft having sufficient payload, a GPS receiver and Intuitive Circuits video overlay board can put the speed, altitude and direction, along with call sign, over the camera video.

3.3 ATV from Near Space

Seeing the earth fall away via ATV as an amateur rocket or balloon rises can be quite exciting as shown in Figure 29. There are a number of groups sending up balloons and rockets with instrumentation, beacons and repeaters in addition to ATV. Balloon transmissions have been received as far as 500 miles away as the instrument package rises to 100,000 ft before the balloon pops from gas expansion and ultra violet decomposition and then parachutes back to earth. Radio direction finding clubs are often asked to help find where the balloon has come down and aid in recovery.

Rockets and balloons using ATV present a challenging optimum antenna radiation pattern problem similar to satellites that are predominantly flown overhead. For strongest picture and best distance (DX), the transmit and receive antennas should have their major

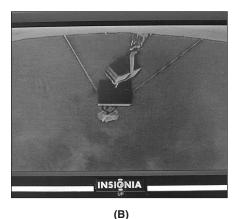

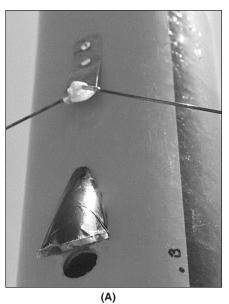

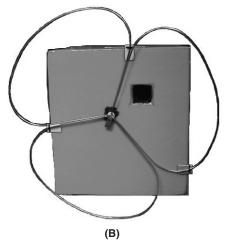

Figure 29 — At (A), an ATV camera view from a balloon at 93,399 feet shows the blackness of space, the curvature of the earth and hazy clouds below. Note that the standard NMEA altitude data output from GPS receivers is in meters. At (B), video received from a balloon on a 7 inch portable LCD TV at 20 miles slant distance. The camera is looking down at the instrument package, with clouds and the ocean below.

power lobes pointed at each other and use the same polarization.

An omnidirectional vertical dipole antenna in the vehicle is fine for best DX on the horizon where the receiving station views the vehicle from a low angle. For example if a rocket is expected to go 1 mile vertically, receiving stations at 4 miles or more away will be within the maximum radiation lobe of the antenna and get the best video. Receiving stations at the launch site or closer than 4 miles away would be within pattern nulls.

If the rocket antenna is a 1/4 wave vertical spike on the nose and the body of the rocket is the ground plane, the main lobe can have an up-tilt of 15 to 20° above the horizon and a significant amount of the signal will be wasted. Balloons can use an upside down ground plane hanging below the instrument

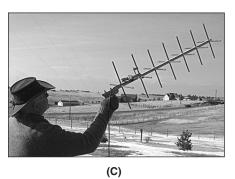

Figure 30 — At (A), a dipole antenna and a mirror are mounted on the outside of a 3.5 inch diameter amateur rocket. A video camera inside looks through the hole to the mirror so those receiving can see the view of the ground fall away as the rocket blasts off. At (B), N8UDK mounted an Old Antenna Lab 70 cm Little Wheel horizontal omni antenna to the bottom of his high-altitude balloon ATV payload. The camera is mounted inside the insulated foam package and looks out through the square cutout. At (C), a handheld antenna using circular polarization can be pointed at a balloon or rocket for maximum signal level as it travels. See www. hamtv.com/rocket.html.

package to give a down tilt to the earth below.

At the launch site, a horizontal dipole on the rocket (see **Figure 30**) and circularly polarized antenna on the ground works best. Balloons do well by hanging down an omnidirectional wheel antenna that is horizontally polarized on the horizon, but circularly polarized directly below. Circular polarization at one end helps to minimize the signal strength variation as the vehicle spins.

An adjustable power 5-W, 70 cm ATV transmitter module such as the Videolynx VM-70X is a good tradeoff between power and battery weight. Balloon flights are typically over many hours and the temperature and heat dissipation vary greatly. A 50K thermistor is added to the VM-70X at the RF

Power adjust pot trace to ground to reduce the power when the module gets too hot, but brings it back up in the cold altitudes. A beam antenna for reception is necessary to make up for the low power if you want snow-free pictures from higher than 20,000 ft. Typically, ATV equipment is housed in an insulated enclosure suspended below the helium-filled balloon, along with a battery capable of lasting the expected length of flight time. Styrofoam is light and will retain some of the heat dissipated from the electronics so that the extreme cold at altitude does not cause the transmitter and battery to cease operation. However, the heat from the ATV transmitter needs to be partially ducted outside the foam package with a sheet of copper. See the **Telemetry and Navigation** chapter for more information on balloon platforms.

Balloon and rocket groups have a lot of how-to information and often announce when there will be a launch so that hams within a few hundred miles radius can try receiving the signals. Some groups are:

4 Video Sources

Practically any video device that delivers a picture when plugged into the coaxial video jack of a video monitor can be plugged into an ATV transmitter and used to send video over the air. Suitable sources include the composite video from camcorders, video cameras, digital cameras, VCRs or computers. The standard A/V cable from a video device has a phono plug on the end and is often identified by yellow color coding (other colors are used for audio).

The cost of video cameras has come way down, thanks to the development of solid state imaging devices that vary in size, type and number of horizontal and vertical picture elements (pixels). Cameras widely available for home video work well for ATV.

VIDICON TUBES

The vidicon is a relatively simple, inexpensive vacuum tube imaging device that once was the standard for home video cameras, closed-circuit television and ATV applications. Figure 31 shows a vidicon's physical construction. As with a cathode ray tube (CRT), an electron beam is created by a cathode and accelerated by grids. Horizontal and vertical deflection of the electron beam in a vidicon is accomplished with magnetic fields generated by coils on the outside of the tube. Varying the strength of the fields control the beam's position as it scans across the inside of the front of the vidicon, which is coated with a photoconductive screen layer. As the electron beam scans the screen, it charges each spot on the screen to the cathode voltage (about -20 V with respect to the signal electrode). Each spot acts like a leaky capacitor, discharging when illuminated by light hitting the front of the vidicon. The rate of discharge depends on the intensity of light illuminating the spot.

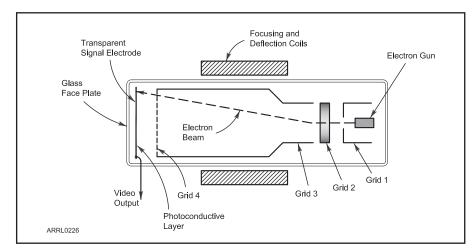

Figure 31 — The construction of a vidicon tube used for acquiring video images. Light striking the front of the tube causes the current in the electron beam from the cathode to photoconductive layer to change. These changes create the electronic video signal.

When it next scans across the spot, the electron beam will deposit enough electrons to recharge the spot to cathode potential. As it does so, the current flowing between the cathode and the screen increases, proportionally to how much the spot's "capacitor" discharged since last being scanned by the beam. Since this discharge depends on the amount of light hitting that spot on the screen, the changes in the beam current as it scans the screen correspond to the image being viewed by the screen. This creates a video signal that represents the scanned image. The variations in the beam current are very low (a fraction of a microamp), and the output impedance of the vidicon is very high, so the video circuitry must be designed with care to minimize hum and noise and the tube itself must be carefully shielded.

CHARGE-COUPLED DEVICES

A charge-coupled device (CCD), in its simplest form, is made from a string of small capacitors with a MOSFET on its input and output. The first capacitor in the string stores a sample of the input voltage. When a control pulse biases the MOSFETs to conduct, the first capacitor passes its sampled voltage on to the second capacitor and takes another sample. With each successive control pulse, the input samples are passed to the next capacitor in the string. When the MOSFETs are biased off, each capacitor stores its charge. This process is sometimes described as a "bucket brigade," because the analog signal is sampled and then passed in stages through the CCD to the output.

Figure 32 shows a two-dimensional CCD

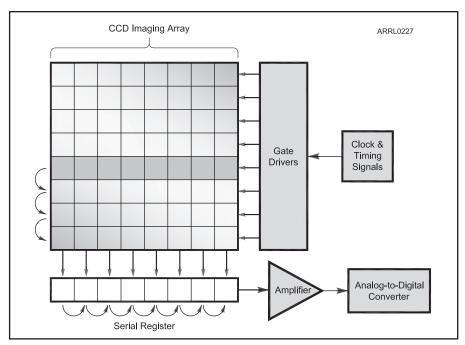

Figure 32 — The construction of a two dimensional CCD array that might be used in a digital camera. When a control pulse biases the array to conduct, the first row passes its sampled voltage on to the next row and takes another sample. With each successive control pulse, the input samples are passed to the next row until they reach the edge of the array. There they are transferred to a serial register and digitized

that might be used in a digital camera. In a CCD used for imaging, an array of sensing elements called pixels are coated with lightsensitive material. The light-sensitive material in each pixel photocharges a single CCD capacitor. The photogenerated charge on each capacitor is proportional to the amount of light striking the sensing element. The stored charges are then shifted out of the CCD array a line at a time as signals corresponding to each pixel. The resulting sequence of signal is similar to that of a vidicon scan. CCDs are the most common imaging device used in digital photographic cameras as well as video cameras, and they have very good low-light sensitivity.

Color CCDs use a screen, called a Bayer mask, over each square of four pixels. Each square has one for red, one for blue and two for green because the human eye is more sensitive to green. The luminance — gray scale — is sampled from every pixel. The possible lines of vertical resolution are determined by the number of pixels horizontally, but color resolution will be less because it comes from a square of four pixels.

When *lines of resolution* are given for a camera, this refers to the number of changes from vertical black lines to white that can be

seen horizontally across the picture. While it is good to have a higher resolution camera — most are 380 lines or more — the picture will still be seen on a TV or monitor. In these display devices, response bandwidth limits luminance to about 240 lines and color to 100 lines in the NTSC system.

CMOS CAMERAS

CMOS active pixel sensors are a newer development and are replacing CCDs in imaging products. CMOS cameras have lower current requirements, lower price and less image lag, making them popular in cell phones. Amateurs use them for portable ATV applications such as the hat cam in **Figure 33**. A small CCD color camera may draw 120 mA while a comparable CMOS version draws 50 mA.

At first glance, board-level cameras are lighter for weight-sensitive applications like R/C and balloon vehicles, but those housed in a metal case are preferred to afford shielding from the effects of RF getting into the circuitry. The CMOS camera shown in **Figure 34** only weighs 3 oz in a 1.5-inch square metal case. It also includes a mic with line level audio output.

Figure 33 — Michael Saculla, K6MDS, built an ATV Hat Cam — www.hamtv.com/hatcam.html — using a CMOS color camera along with a Videolynx 70 cm transmitter for public service applications.

Figure 34 — The tiny LB-1000 420-line CMOS color camera is typical of the many low-cost devices available. Intended primarily for security applications, they are popular with amateurs.

5 Glossary of ATV Terms

- Aspect ratio Image width divided by its height. Standard definition analog television uses an aspect ratio of 4:3 and broadcast HDTV uses 16:9.
- ATSC Advanced Television Systems Committee, the group that defined the set of standards and formats for the digital television formats implemented in the Broadcast Television Service. See DTV.
- ATV Amateur Television. Sending pictures by Amateur Radio. You'd expect this abbreviation to apply equally to fast-scan television (FSTV), slow-scan television (SSTV) and facsimile (fax), but it's generally applied only to FSTV.
- Back porch The blank part of a scan line immediately following the horizontal sync pulse. See blanking.
- **Black level** The signal level amplitude that corresponds to the black end of the video dynamic range.
- Blanking A "blacker-than-black" signal level that assures that the scanning trace cannot be seen as it is reset to scan another line or frame. In conventional television this is often referred to as the blanking pedestal, consisting of two segments the front porch that precedes the vertical sync pulse and the back porch that follows the sync pulse.
- Cathode ray tube (CRT) A specialized electron tube, employing a phosphorcoated screen, used for image display. The classic TV "picture tube" used in older television sets and computer monitors, is an example of such a tube.
- Charge-coupled device (CCD) An integrated circuit that uses a combination of analog and digital circuitry to sample and store analog signal voltage levels, passing the voltages through a capacitor string to the circuit output.
- Chrominance The color component of a video signal. NTSC and PAL transmit color images as a black-and-white compatible luminance signal along with a color subcarrier. The subcarrier phase represents the hue and the subcarrier's amplitude is the saturation.
- CODFM Coded Orthoganal Frequency Division Multiplex. A system of a large number of carriers as is used with DVB-T. See en.wikipedia.org/wiki/CODFM.
- Color burst Seven cycles of a 3.58 MHz subcarrier signal located on the back porch (see blanking) of an NTSC color TV signal waveform. This short burst is locked on to by a PLL in the TV receiver as the reference for the chroma in the video.
- **Color subcarrier** The modulated 3.58 MHz component of an NTSC color tele-

- vision signal that is used to convey the color or luminance image data.
- Composite video The standard 1 V peak to peak analog video into 75 Ω load signal consisting of color, video, blanking and sync found in consumer products and typically identified with a yellow color coded RCA connector. The sync tip is referenced at 0 V, blanking at 0.285 V, black level at 0.339 V and white at 1.0 V
- **Compression** Various digital techniques to reduce the bandwidth, transmission rate or file size of an image.
- Constellation Type of modulation within the specified bandwidth. i.e. QPSK or QAM.
- Deflection the circuits or other components controlling the vertical and horizontal sweep signals that move the scanning beam of a cathode ray tube image display.
- DTV Digital television, most commonly applied to a series of 16 digital formats (including HDTV or High Definition Television) that comprise the default commercial broadcast digital TV standards in the United States.
- **DVB-S** Digital Video Broadcast Satellite.
- **DVB-T** Digital Video Broadcast Terrestrial.
- FEC Forward Error Correction. A code rate used in DVB-T. 7/8 means 7 data bits for each single FEC bit.
- FFT Fast Fourier Transform is an algorithm used for time and frequency synchronization of the DVB-T carriers. 2K and 8K DVB-T modulator parameter denotes 1705 and 6817 carriers respectively.
- Field Collection of top to bottom scan lines. When interlaced, a field does not contain adjacent scan lines and there is more than one field per frame.
- Frame One complete scanned image. NTSC has 525 lines per frame with about 483 usable after subtracting vertical sync and a few lines at the top containing various information.
- *Front porch* The blank part of a scan line just before the horizontal sync.
- FSTV Fast-Scan TV. Same as common, full-color, motion commercial broadcast TV.
- Guard Interval The space between symbols or characters and is important for minimizing the effects of multipath. 1/16 means there is one guard space preceding each 16 symbols.
- *H.*264/*MPEG-4* A video compression standard used with DTV modulators,

- recording and video content. See en.wikipedia.org/wiki/H.264.
- Interlaced scanning A scanning pattern, designed to reduce perceived flicker in broadcast television systems, in which the complete image frame is actually made up from two sequentially-scanned fields and thus improving the vertical resolution. The timing of the sequential scanning is such that the lines of the second field are interspersed between the lines of the first field. For example, NTSC sends a field with just the even lines in 1/60 second, then a field with just the odd lines in 1/60 second.
- Luminance The brightness component of a video signal and can refer to the white-to-black amplitude or the chroma weighted sum of the gamma-compressed R'G'B' components computed as Y (the luminance signal) = 0.59 G (green) + 0.30 R (red) + 0.11 B (blue).
- MPEG Motion Picture Experts Group, a set of digital image compression formats/standards for moving images.
- MPEG-2 A compression format standard for video and audio widely used with DVDs. See en.wikipedia.org/wiki/ MPEG-2.
- NTSC National Television System Committee. Analog broadcast television standard used in North America and Japan.
- PAL Phase alteration line. Analog television standard used in Germany and many other parts of Europe.
- PID Packet Identifier in a DVB-T data transport stream is similar to CTCSS with FM voice.
- Progressive scanning A scanning sequence in which all image lines are scanned sequentially to display the complete image frame. Used in some DTV broadcasts.
- Pixel Picture element, the dots that make up images on a monitor. Image resolution is directly related to the number of picture elements. If the size of a picture element is large relative to total image size, the image will be made up of a relatively small number of picture elements and thus have relatively poor resolution. If the size of a picture element is small relative to total image size, the image will consist of a large number of picture elements and thus demonstrate better resolution.
- Raster The pattern of scanning lines developed on the face of a cathode ray tube during the display of one image frame.

Resolution — The ability to see a number of vertical lines horizontally across the screen. The NTSC analog horizontal scan rate of 15734 Hz limits the luminance resolution to 80 lines per MHz of video response bandwidth. Digital TV's highest resolution is limited by the number of screen pixels. It takes 2 adjacent pixels, one black and one white for one line.

RGB — Red, Green, Blue. One of the models used to represent colors. Due to the characteristics of the human eye, most colors can be simulated by various blends of red, green, and blue light.

SECAM — Sequential color and memory.
 Analog television standard used in
 France and the Commonwealth of
 Independent States.

Sync — That part of a TV signal that indicates the beginning of a frame (vertical

sync) or the beginning of a scan line (horizontal sync).

Vidicon tube — A type of photosensitive vacuum tube used in TV cameras.

White level — The white end of the video dynamic range in any image transmission format. The difference between white and black levels defines the video dynamic range of the mode.

8-VSB — 8-level Vestigial Side Band, the standard for broadcast **DTV** in the US.

6 Slow-Scan Television (SSTV) Overview

The previous sections discussed fast-scan amateur television, used to send wide-bandwidth full motion video on the 420 MHz and higher frequency bands. In contrast, slow-scan television (SSTV) is a method of sending still images in a narrow bandwidth widely used on the HF bands. SSTV activity can be found on HF, VHF, UHF, repeaters, satellites, VoIP on the Internet, and by almost any means that can transmit and receive a voice signal.

Images are our most powerful communication tool. SSTV allows us to add images to our verbal communications via Amateur Radio. Working with the SSTV mode can provide much more than just swapping pictures. It provides a practical way to learn about radio propagation, computers and computer graphics. As with any activity, the more involved you become, the more knowledgeable you become about all the intricacies.

SSTV is also a great way to get others involved in Amateur Radio or enhance other activities. Consider adding SSTV capability to your emergency communications, public service, Field Day or Jamboree on the Air station. SSTV is a legacy mode that is enjoyed by many hams worldwide. More and more hams are finding this older mode appealing and it is

also used by public service teams to support disaster response and recovery efforts.

This section of the *Handbook* is intended to provide an overview of SSTV signals, operation, and equipment configuration. The *SSTV Handbook* by Martin Bruchanov, OK2MNM, is a very thorough resource on all aspects of SSTV and may be downloaded at **www.sstv-handbook.com**.

Figure 35 — First cross-Atlantic SSTV transmission in 1959.

6.1 SSTV History

SSTV originally involved the transmission of a visual image from a live video source. Images were black-and-white. Specific audio tones represented black, white, and shades of gray, and other audio tones were used for control signals. The receiving station converted the tones back into an image for display on a picture tube. It took 8 seconds to send a picture, and everything fit in the same bandwidth used for SSB transmissions.

Cop Macdonald, WA2BCW, now VY2CM, developed the first SSTV system. Macdonald received the Dayton Hamvention's Technical Excellence Award in 2009 for his SSTV development work. **Figure 35** shows the first SSTV image sent across the Atlantic Ocean to John Plowman, G3AST, by MacDonald in 1959.

For the initial system, MacDonald used a surplus long-persistence phosphor radar monitor to display the images. The images were captured using a vidicon camera or a flying-spot scanner. One frame of video had 120 lines and was sent at a rate of 15 lines per second, requiring 8 seconds per frame. Three frames were sent back-to-back to maintain an image on the monitor. For many years, bulky

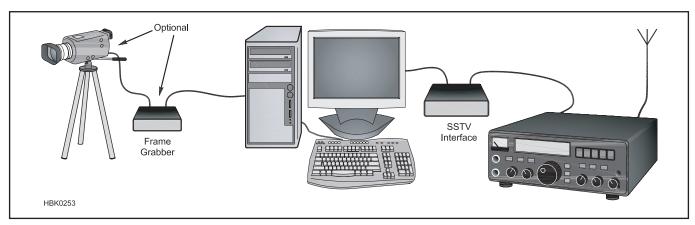

Figure 36 — SSTV stations need only a sound card equipped PC and simple interface to send and receive SSTV.

and complex home-built systems were the only way to participate in SSTV.

Robot Research produced SSTV equipment throughout the 1970s and 1980s. The Robot 1200C scan converter, introduced in 1984, represented a giant leap forward for SSTV — all the SSTV functions were performed within a single piece of equipment. A *scan converter* converts signals from one video format to another. In this case, it converted SSTV signals to and from formats intended for fast scan television. This allowed the use of standard video cameras and equipment to capture and display images.

DOS-based PCs became a popular com-

ponent for SSTV systems in the early 1990s. These hybrid systems were part hardware and part software. Most systems required external equipment to process the audio and perform the analog-to-digital conversion. In 1998, the Tasco Electronics TSC-70 Telereader color scan converter was used on the MIR space station to send pictures from space. Kenwood introduced Visual Communicator VC-H1, a portable SSTV unit that included a built-in camera and LCD monitor. Other scan converters were made, but none are produced today.

The personal computer with a built-in

sound card has become the hardware of choice to send and receive images, replacing specialized devices. Today's powerful PCs and SSTV software are the heart of a modern SSTV station. The PC processes the incoming and outgoing SSTV audio using the sound card, while the software manages the acquisition, storage, selection, and editing of the SSTV pictures. With a PC in your ham station, adding software and an interface (to connect the computer sound card to the transceiver) is all that it takes to get started in this fascinating mode. **Figure 36** shows a typical current station SSTV configuration.

7 SSTV Basics

Traditional SSTV is an analog mode, but in recent years digital SSTV has been developed. Both make use of standard voice Amateur Radio transceivers — no special radio gear or antennas required. SSTV transmissions occupy only the bandwidth of voice signals and are allowed on any frequency in the HF and higher bands where Image emissions are permitted. These are generally the same band segments used for SSB voice signals.

7.1 Computers and Sound Cards

A computer with sound card is required to use most of the software popular for SSTV. Software for the *Windows* operating system is the most popular, but other choices are available. (Software for analog and digital SSTV is discussed later in this section.) Hardware and software setup is similar to that described for sound card modes in the **Digital Communications** chapter of the downloadable supplemental material. The sound card characteristics discussed in the **Digital Communications** chapter apply to SSTV as well. Most sound cards will work, but sample rate accuracy is important for some SSTV modes (more on this later).

Within *Windows*, the MASTER VOLUME and WAVE controls set the levels for the transmitted SSTV audio. All other mixer inputs should be muted. Equalization and special effects should not be used. *Windows* sounds should be disabled to prevent them from being transmitted along with the transmitted SSTV audio. The RECORDING control panel is used to select the input for receiving the SSTV audio. Adjust the LINE IN OF MICROPHONE level settings as needed for the proper level. MIC BOOST should not be used.

7.2 Transceiver Interface

Interfacing the transceiver to the PC sound card can be as simple as connecting a couple of audio patch cables. Sound cards generally have stereo miniature phone jacks, so use matching plugs when making these connections. Only one audio channel is required or desired—the left channel. This is the tip connection on the plug. Use shielded cable with the shield connected to the sleeve (ground) on the plug. Ground loop problems may be avoided by bonding equipment together or by using an audio isolation transformer. (See the Digital Communications chapter for examples of how to connect the transceiver and PC. Another useful resource is the sound card interface web page by Ernie Mills, WM2U, at www.w0btu.com/wm2u/interface.html.)

The connection for received SSTV audio from the transceiver may be made anywhere that received audio is available. The best choice is one that provides a fixed or *line level* audio output. This will ensure that recording control levels will not have to be adjusted each time the volume on the transceiver is adjusted. You can use a headphone or speaker output if that's all that is available. If the received output level is enough for the LINE IN input on the sound card, use it, otherwise use the MICROPHONE input. If the level is too high for LINE IN, an attenuator may be required.

Use the LINE OUT connection on the sound card for transmitted SSTV audio. (See the **Digital Communications** chapter's examples for AFSK signals.) If the transceiver does not have a separate input for the audio signal, the microphone input must be used. This requires a more elaborate interface. Transmitreceive (TR) keying can be controlled using the transceiver's VOX. Other methods for activating transmit include manual switching, a serial port circuit, an external VOX circuit, and/or a computer-controlled digital

signal output.

Fully-assembled and kit sound card interfaces are available commercially. Most of the sound card interfaces for the digital modes are suitable for SSTV. The microphone will be used regularly between SSTV transmissions, so consider how to conveniently switch back and forth between voice and SSTV operation.

7.3 Transceiver Requirements

An SSB voice transceiver with a stable VFO is necessary for SSTV operation. The VFO should be calibrated and adjusted to be within 35 Hz of the dial frequency (more on this later). The transceiver's audio bandwidth should not attenuate the audio spectrum used by SSTV. Filters should be set to 3 kHz or wider. Turn off functions that affect audio bandwidth or linearity, such as transmit or receive audio equalization, noise blanker or noise reduction functions, compression or speech processing, and passband tuning or IF shift.

Adjust the transmitter output for proper operation with the microphone first, according to instructions in your manual. Then connect and adjust the sound card output for the desired audio level. Properly adjusted levels and clean audio quality will improve the reception of the transmitted signal as well as reduce interference on adjacent frequencies.

SSTV transmissions are 100% duty cycle when an image is being sent. If your transceiver is not designed for extended full-power operation, reduce the power output to one-half its maximum output.

SSTV may be transmitted using AM, FM or SSB. Use the same mode as you would use for voice operation on a given frequency. On HF, use the same sideband normally used for voice on that band.

7.4 SSTV Operating Practices

Analog SSTV images are, in a sense, broadcast. They are received without error correction or transmission acknowledgement and do not require the recipient to establish a two-way connection. The majority of SSTV operation takes place on 14.230 MHz (more on alternate SSTV frequencies later).

You can establish a contact by voice first before sending the SSTV image, or just ask if the frequency is in use. If the frequency is clear, you can send an SSTV transmission as your CQ. Listen carefully as a station might be sending but you cannot hear them due to propagation. Receiving SSTV images will take place automatically as long as your software supports the mode used for transmission (more on SSTV modes in later sections). Once a picture is received, it will be displayed and may be saved. Some software displays the image as it being received.

When selecting images to send, consider appropriateness, picture quality, and interest to the recipient. Choose an SSTV mode that is suitable for the image to be sent and band conditions. Avoid using ScottieDX or other SSTV modes which require more than 2 minutes of transmission time to avoid occupying the frequency for an excessive period. Sending a CW or voice station ID is not necessary if your call sign is included in the image.

To send a SSTV image, use your software to select and load a picture to send. It will be displayed in a transmit screen. Next, select the SSTV transmission mode. Initiate the transmission and your transceiver will switch to transmit and send the SSTV audio. When the SSTV transmission is over, the transceiver returns to receive. Be sure to send the full frame or the next picture sent may not be received properly if the software does not start scanning from the start of the frame.

SOURCE FOR IMAGES

The internet is a popular source for images (pay attention to copyright notices). You can develop and store picture collections by theme, such as airplanes, landmarks, moonlit scenes, or holidays.

A digital camera is one of the best ways to create an original picture of your own. The subject matter could be almost anything that you might have available. Pictures of the shack, equipment, and operator are always welcomed. A live camera or web cam can provide a quick snapshot. For those who like to discuss technical details, diagrams and schematics might be your chosen subject. A flatbed scanner is ideal for importing diagrams, schematics, and photographs. Screen shots of what is on the computer monitor can be saved simply by using the PRINT SCREEN or PRTSCRN key. Use the Paste function in Windows to transfer the image to your SSTV or image editing software.

Include your own personal drawings. Make your images colorful with lots of contrast to make them really stand out. You can also transmit pictures of your home, areas of local interest, other hobbies, projects, maps, cartoons, and funny pictures.

Any image editing program can be used to make your own CQ image, test pattern, video QSL card, or "73" picture. Use the JPG or BMP image format and crop images to 320 \times 256 pixels.

It is common to have call sign, location, and perhaps a short description as text on the pictures. If two call signs are placed on an image, it is understood that the sender's call sign is placed last. Signal reports may also be included. This information is not typically embedded in the image. Instead, the SSTV software has a text editor to overlay this variable data on to the selected picture before each transmission.

8 Analog SSTV

SSTV is a video mode that uses analog frequency modulation. Every different brightness level in the image corresponds to a different audio frequency. The modulating frequency ranges from 1500 to 2300 Hz, corresponding to the brightness of the video component. The frequency of video signal

varies from black by shades of gray to white. The amplitude of the signal does not affect the brightness, only the signal-to-noise ratio (SNR) of the signal. Color is achieved by sending the brightness of each RGB color component separately. The original image is scanned from left to right, in green, blue and red order for Martin and Scottie modes.

Although SSTV is an image signal mode, the format of the signal by which brightness and color are encoded is also called a mode. The various modes have different resolutions and scan rates.

Table 2 contains a summary of SSTV ana-

		S2	RGB	71 s	240*

*Martin and Scottie modes actually send 256 scan lines, but the first 16 are usually grayscale. Data courtesy of Wikipedia's entry on Slow-Scan Television at en.wikipedia.org/wiki/Slow-scan_television log modes for both black and white (B&W) and color. Color SSTV images are the standard today. (See the chapter "Formats of slow-scan TV transmission" in OK2MNM's SSTV Handbook in the references listings for a complete description of SSTV image signals.)

8.1 Color SSTV Modes

Two popular modes for sending and receiving color SSTV pictures are called Martin and Scottie (named after their developers — see Table 2). During a three-day study in 2014, 89 percent of the images received worldwide at WB9KMW were from these two modes. Within each family are several different varieties, for example Martin 1, Martin 2, Scottie 1, and Scottie 2.

Information about the size or resolution for each mode is generally available in the SSTV software. Slower scan rates can provide better quality; those are the modes that take longer to send for the same resolution.

For example, Scottie 1 and Martin 1 are popular RGB (red, green, blue) color modes that take about two minutes to send a frame. The image size sent is $320 \times 256 - 320$ pixels across with 256 lines. See **Figures 37** and **38**. True color is possible since each pixel is sent with 256 possible levels for each of the three different color components, red, green and blue.

Each mode has a *vertical interval signal-ing* (VIS) code that identifies the mode being sent. The code is sent during the time between frames, called the *vertical interval*. The VIS codes use 1100 Hz for 1, 1300 Hz for 0, and

1200 Hz for start and stop. When a VIS code is received, receiving system configures itself for the proper SSTV mode.

For VIS code detection to work, the receiver must be tuned within 70 Hz of the transmitted frequency. Two stations tuned exactly on the SSTV frequency but with VFO errors of +35 Hz and -35 Hz could successfully pass the VIS codes. As mentioned previously, each transceiver must have the VFO and display calibrated within 35 Hz to ensure VIS code detection with the transceiver set to the SSTV frequency. Using the sync pulse rate is another way to determine the mode when the VIS is not decoded. If a station sending is far off frequency, use the 1200 Hz sync signal in the spectrum or waterfall as a guide to adjust the VFO.

Received images are displayed in near real time as they are decoded. Almost any SSTV signal that is heard can produce an image, but it is rare to receive an image that is perfect. Changes in propagation, noise, and other interferences will become apparent as the image continues to scan down the screen. Noise will damage the lines received just as it occurs. Interference from other signals will distort the image or perhaps cause reception to stop. Signal fading may cause the image to appear grainy. Multipath will distort the vertical edges. Selective fading may cause patches of noise or loss of certain colors.

Images that are received with staggered edges are the result of an interruption of the sound card timing. Check with other operators to see if they also received the image with staggered edges. If not, then it may be your computer that has the problem and not

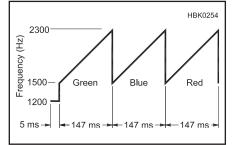

Figure 38 — This is a diagram of a single scan line of a Martin 1 transmission. The full frame includes 256 horizontal scan lines starting at the top. Before each line, a 1200 Hz tone for 5 ms is sent for synchronization. The pixels are scanned left to right and the colors are sent sequentially. First the green component is sent for each of the 320 pixels of one scan line — 256 values are possible from black to pure green. Next, is the blue component, and the red component is sent last (again, 256 possible values for each color), It takes 147 milliseconds to send each of the three color components. The result is 114 seconds to send the complete frame.

the sending station. Some possible solutions are to close other programs, disable antivirus software and reboot the computer.

8.2 Communicating in Color

While an image transmitted from the home station may appear very attractive at the sending station, it can be very difficult or impossible to view on the receiving end. Signals often deteriorate significantly due to propagation, noise and other factors. The operator can take steps to maximize the received image quality. The two most important factors are font size for characters and color contrast.

First, choose a large text font so the text can be read even in the presence of noise. Then for high visibility and readability of text in the image, high contrast is crucial. Problems arise from the choice of pastels and less than distinct color combinations. The top four most visible color combinations are black text on a yellow background, black over white, yellow over black and white over black.

When attempting to communicate effectively via SSTV, do the following:

- Keep it simple. Keep the wording short and succinct.
- Keep it big. Large text allows hams to view your message clearly.

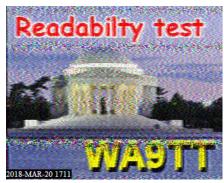

Figure 39 —Text is easiest to read when properly sized and contrasts well with the image background.

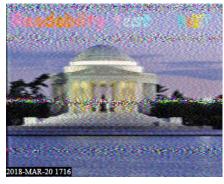

Figure 40 —This image is harder to read due to poor choice of font size and color contrast in the presence of noise artifacts in the received image.

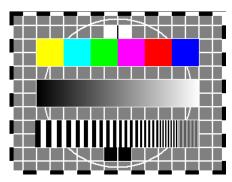

Figure 37 — This color test pattern is 320×256 resolution. The Robot modes from the 1980s only used 240 lines. CRTs were 4:3 aspect ratio, so the images were displayed in 320×240 resolution. When Scottie 1 and Martin 1 modes were added, they kept this resolution but added 16 header lines to the top to aid in synchronization. These 16 header lines, shown as the solid gray area at the top, are now used as part of the image and include the sender's call sign and other information.

- Keep it clean. Avoid using thin fonts, as well as most script fonts. Use thick, heavy fonts to maximize readability.
- Keep it colorful. High color contrast is the key ingredient.

Figures 39 and 40 illustrate how readability is affected by font size and color contrast, as copied by a distant station. Both images carry the same text message.

8.3 SSTV Signal Reporting

Traditionally, hams have used an RSV system to give an SSTV signal report. This parallels the RST report given on CW and RS for SSB contacts. RSV denotes:

- Readability for the template words
- Strength of the transmission
- Video quality

R=5 is perfectly readable text. S=9 denotes an extremely strong signal. V=5 means the video is crystal clear without any blemishes. Although 595, 575, and the occasional 555 report are given, a true V=5 image is fairly rare. Thus, the traditional RSV signal reporting system does not provide a lot of information to the transmitting station operator.

An alternative SSTV reporting P-quality system is gaining in popularity similar to the reporting system for fast-scan ATV. There are six levels from P5 to P0. These levels are based on image research that assigned data quality rating compared to an original image.

- P5: 100% to 97.7% received, broadcast quality with minimal distortion. See **Figure 41**.
- P4: 97.7% to 84.1% received, a good image with a few noise lines. See **Figure 42**.
- P3: 84.1% to 50% received, the most common image quality on 20 meters. These pictures are usable but noisy. See **Figure 43**.
- P2: 50% to 15.9% received, the SSTV signal is not strong enough to overcome the noise. These images are quite noisy and barely usable. See **Figure 44**.
- P1: 15.9% to 2.3% received, images during poor signal reception. One can barely see the text and the picture is far from distinct. See **Figure 45**.
- P0: 2.3% to 0% received, images are totally unusable. See **Figure 46**.

8.4 SSTV Cams

A few hams around the world routinely monitor SSTV transmissions, typically on 14.230 MHz, and then immediately post that information on their website servers for display on web pages. These sites are referred to as "SSTV cams." Similar to the Reverse Beacon Net (RBN), PSKReporter, and WSPRNet systems, some stations go further by collecting SSTV cam images and aggregating those images onto one web page for viewing.

This information is helpful in two ways:

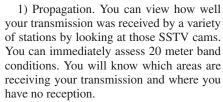

Figure 41 — P5: Broadcast quality

Figure 42 — P4: Good, some noise

Figure 43 — P3: Usable, but noisy.

2) Station relay. When you are in the midst of an SSTV QSO, all sorts of things happen, such as QSB, QRM, and QRN. All interfere with your ability to receive the latest transmission. By using these SSTV cams as "relay stations" to supplement your station's reception, you will be able to enjoy a richer QSO.

There are a few major websites around the world which offer a variety of SSTV cams for your viewing, such as:

Figure 44 — P2: Barely usable, noisy.

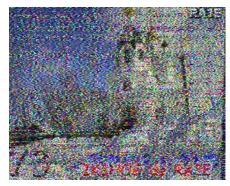

Figure 45 — P1: Text is barely visible.

Figure 46 — P0: Unusable

8.5 SSTV Operating Frequencies

SSTV operation centers on several frequencies in the HF and VHF range. Use the customary phone sideband for the band being used. Most contacts occur on 20 meters on 14.230 MHz for analog SSTV and on 14.233 MHz for digital SSTV. (Move 3 kHz above or below these frequencies to have an extended contact if the band is busy.) **Table 3** lists a number of popular frequencies used in North

Table 3
SSTV Frequencies
Analog

15

Band (Meters)	Frequency (MHz)	Modulation
160	1.890	LSB
80	3.845, 3.730 in Europe	LSB
40	7.171, 7.040 in Europe	LSB
20	14.230	USB
17	18.117	USB, N-SSTV (see text)
15	21.340	USB
12	24.927	USB, N-SSTV (see text)
	24.975	USB, All modes
10	28.680	USB

ISS SSTV Downlink	145.800	FM
Digital		
Band (Meters)	Frequency (MHz)	Modulation
80	3.843, 3.733 in Europe	LSB
40	7.173	LSB
20	14.233	USB

USB

America and Europe. Remember that these frequencies are not dedicated to SSTV and may be occupied with other signals. Having a backup frequency or using another band to avoid congestion is good practice.

21.343

In the late afternoon and evening hours, regional activity switches to 40 and 75 meters, with some contacts on 160 meters. In the United States, 7.171 MHz and 3.845 MHz are commonly used, although 7.171 MHz is only available to Extra Class licensees.

Locally, a 2 meter SSTV net may be active either on the SSTV calling frequency of

145.500 MHz or perhaps on an FM repeater. (Before using a repeater for SSTV contacts, be sure the repeater owner approves.)

Occasionally the International Space Station will broadcast SSTV pictures on 145.800 MHz. Check **ariss-sstv.blogspot.com** for the operating schedule. A simple antenna and a common FM transceiver can be used for reception as shown in **Figure 47**. ISS passes visible at your location can be determined by a satellite tracking program or via a website such as **heavens-above.com**.

Figure 47 — Image received from the International Space Station.

8.6 Narrow SSTV

Due to crowded conditions on 20 meter SSTV, "Narrow SSTV" or N-SSTV has become popular. This is an analog SSTV transmission with an audio signal only 500 Hz wide, extending from 1900 to 2300 Hz. Contrast that with normal SSTV, which has a VIS marker at 1200 Hz and image intensity is transmitted between 1500 and 2300 Hz.

It is useful to enable your software to use the FSKID method of call sign identification during the transmission. The PLL demodulation technique seems to work best for receiving N-SSTV pictures.

N-SSTV is acceptable on the usual SSTV operating frequencies and on 17 meters. It may be used on the 12 meter band as long as you follow the requirements of FCC Part 97.307(f):

- (1) No angle-modulated emission may have a modulation index greater than 1 at the highest modulation frequency.
- (2) No non-phone emission shall exceed the bandwidth of a communications quality phone emission of the same modulation type.

There has been some discussion of using N-SSTV on the 30 meter band. The ARRL's understanding of the FCC rules is that image transmissions of any type are not permitted on 30 meters, regardless of whether the transmission encoding is digital or analog. For that reason, the ARRL does not include 30 meters in Table 3.

8.7 Software for Analog SSTV

A variety of software programs are available for SSTV (see **Table 4**). Some multimode programs include SSTV and digital modes, while others are dedicated to SSTV. One very popular SSTV package is the *Windows* program *MMSSTV* by Mako Mori, JE3HHT. For more information or to download a copy, visit **hamsoft.ca/pages/mmsstv.php**. *MMSSTV* will run on an old 100 MHz PC, but some features may require a faster processor. Other SSTV software has similar features.

As explained in the **Digital Communications** chapter, sound card sample rate accuracy is important for some modes. Analog SSTV is one of them: pictures will appear *slanted* if the clock is off. (See **Figure 48**.)

The MMSSTV Help file includes detailed information on several ways to do a quick and easy calibration (see the Slant Corrections section). The best method is the one that uses a time standard such as WWV. (Before performing this calibration procedure, you must have the sound card interface connected so MMSSTV can detect received audio.) After performing the clock calibration, chances

are, the timing will also be correct for transmit. If not, MMSSTV provides a means for making a separate adjustment for transmit. Alternatively, two alternative approaches for adjusting receive and transmit slant are discussed in depth in tutorials at wa9tt. com titled "That Pesky Slant." Help for analog SSTV is available on Yahoo Groups MM-SSTV: groups.yahoo.com/groups/ MM-SSTV.

9 Digital SSTV

Several forms of digital SSTV (DSSTV) have been developed, but the modulation method most widely used for digital SSTV is derived from the shortwave broadcast system Digital Radio Mondiale (DRM). (Mondiale is a French word meaning "worldwide.") Like analog SSTV, a majority of activity occurs on 20 meters, specifically on 14.233 MHz. (See Table 3.)

HamDRM by Francesco Lanza, HB9TLK, is a variation of DRM that occupies a 2.5 kHz bandwidth and is used in various programs. The signal occupies from 350 to 2750 Hz (see Figure 49). As many as 57 subcarriers may be transmitted simultaneously, all at the same level. Three pilot carriers are sent at twice the level as the others. The subcarriers are modulated using coded orthogonal frequency division multiplexing (COFDM) and quadrature amplitude modulation (QAM). Each main service channel (MSC) frame or segment has a duration of 400 ms and several methods of error correction are used within the segments. (See the **Modulation** chapter for more information on ODFM and QAM.)

HamDRM is not a weak-signal mode like the narrow bandwidth data modes such as PSK31. An S-9 or better signal with little or no noise may be required before the software is able to achieve a sync lock. MSC sync lock is required before any data can be decoded and displayed.

The quality of a DSSTV signal far exceeds that of analog SSTV. Distortion-free images are exact reproductions of the original transmission. However, there are drawbacks:

- 1) Band conditions. They must be favorable for reception and clear of most QRM and no significant QSB. Strong signals ensure quality reception.
- 2) Sufficient data segments must be received. When an insufficient number of segments are received, the software will simply fail to decode and no image will be seen. Contrast that to analog SSTV where a weak image, perhaps P2 quality, can still be displayed even with strong noise or interference. Transmit encoding may be changed to send duplicate or redundant segments. Normally a setting of RS1 or RS2 is used. When band conditions aren't good, a higher setting of RS3 or RS4 may be used, however, this increases the transmission time. A receiving station may request re-transmission of missing segments via a BSR, or Bad Segment Request. The receiving station transmits the BSR indicating the missing segments to be retransmitted for a "fill" of the picture.

9.1 Digital SSTV Setup

A popular digital SSTV program is *EasyP-al* by the late Erik Sundstrup, VK4AES. Digi-

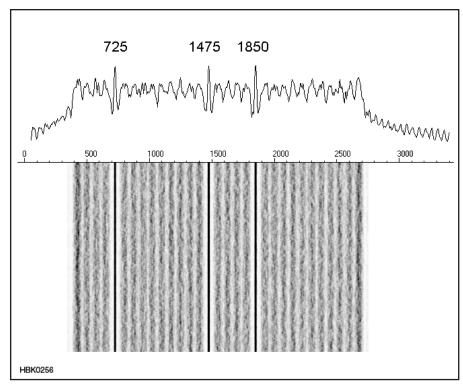

Figure 49 — HamDRM signal spectrum above and waterfall below. Transmissions may have slightly different characteristics due to the many possible submodes. HamDRM transmissions have three pilot carriers with an amplitude twice that of the remaining subcarriers. These pilot carriers are found at 725, 1475 and 1850 Hz and aid in adjusting the frequency of the receiver to match the transmitted signal. Software can compensate for mistuning by as much as ±100 Hz, but only if the offset is stable (little or no drift in frequency). The overall response should be flat, producing a level amplitude across the full spectrum provided that the signal is not affected by propagation. The waterfall should show the same intensity across the full signal. The bandwidth can be as much as 2.4 kHz, starting at 350 Hz and ending about 2750 Hz. Some roll-off can be tolerated.

tal SSTV uses the same type of PC and sound card setup as for analog SSTV, but a more capable computer is required. For *EasyPal*, a 2 GHz or faster PC running *Windows XP* or newer operating system is required. As soon as the *EasyPal* software is installed, it is ready to receive pictures.

Unlike analog SSTV, the software detects and compensates automatically for clock timing differences so sound card calibration is not required. The software also adjusts for ± 100 Hz mistuning.

HamDRM sends the transmitting station's call sign continuously. This may allow others to identify the transmitting station and optimize reception. Many submodes are available, with various transmission speeds and levels of robustness. The submodes are automatically detected and receiving starts automatically. Decoding is done on the fly, so there is no waiting for the computer to finish processing before the image appears.

Power output may appear low as measured by a conventional wattmeter. The actual signal strength as seen by others should be about the same as the SSB voice signal. Do not use dc-blocking capacitors in the audio lines as they may change the phase of the received carriers which disrupts the decoding process.

Audio levels from the sound card to the transceiver are low when using HamDRM and may not trigger a VOX circuit reliably at normal settings. Set the transceiver for full RF output. Then adjust the sound card VOLUME CONTROL output until the transmitter shows little or no ALC indication. With an FM transmitter, keep the output level low to avoid overdeviation. Adjust the VOX GAIN sensitivity for reliable operation.

9.2 Operating Digital SSTV

If you have not operated SSTV before, try analog SSTV before digital. Copy some images to make sure the sound card setup is correct. The level adjustments for analog SSTV are not as critical as those for DRM. Once you have everything set correctly for analog SSTV, it will be easier to make adjustments for digital SSTV.

When using digital SSTV, if a sending station is far off frequency, use the pilot carriers

as seen in the software spectrum display as a guide. (See Table 3 for digital SSTV frequencies.) Adjusting the VFO while receiving an image is not advised as it will delay synchronization.

The signal-to-noise ratio (SNR) displayed in the software is a measure of the received signal quality. The higher the SNR the better—decoding will be more reliable. Because of the way the software measures the SNR, the peak value displayed for SNR may require 20 to 30 seconds of reception. Adjustments made on either end may change the SNR.

Under very good band conditions the SNR may exceed 18 dB. In that case, a higher speed mode may work. Sub-modes with less data per segment take longer to send, but they are more robust and allow for solid copy even if the SNR is low.

GETTING THE WHOLE PICTURE

Noise and fading may prevent 100% copy of all the segments. Any missing segments may be filled in later. Your software can send a *bad segment report (BSR)* that lists all the missing segments for a file that has been partially received. In response, the other station can send a *FIX* (resend bad segment request) which should complete the file transfer. If not, the BSR and FIX process may be repeated.

Digital SSTV is very interactive and may involve several stations on frequency sharing images. FIX transmissions intended for another station may provide some of your missing segments — or even all of them. A third party that copied the original transmission may also send a FIX segment or resend the image. Incremental file repair is possible even after several other transmissions are received. The more stations on frequency, the better the chance that one of them is in a position to help out with a FIX.

EasyPal has a feature to provide a higher level of error correction so that 100% copy of all the segments is not necessary to receive the complete file. The transmitted file is encoded with redundant data so that the original file may be recreated even though not all the segments were received. The receiving station must also be running EasyPal.

Encoded files have interleaved redundancy using Reed-Solomon (RS) error correction. (See the **Digital Protocols and Modes** chapter for more information about error detection and correction.) Four different levels of RS encoding may be selected before the file is sent.

Very Light Encode (RS1) is the lowest level. Transmission time for a file using RS1 will be increased by 13%. When receiving a file encoded with RS1, only 90% of the segments must be received before the file can be decoded and a picture displayed. This may happen even before the transmission is complete. Receiving RS encoded files is

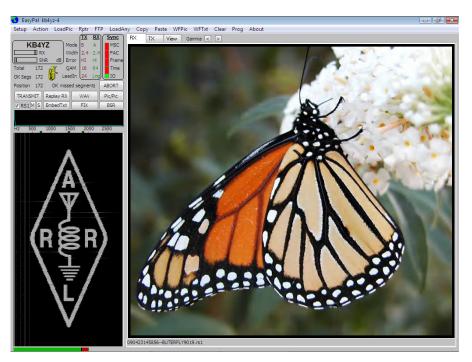

Figure 50 — EasyPal digital SSTV software is used to exchange high quality, color images. Several levels of error correction and various transmission speeds are available.

automatic; there is no need to select it for receive. Decoding of the file received with RS encoding will occur automatically. The use of RS encoding on the HF bands can reduce the need for BSRs and FIXs and has been found to make the file transfer process more efficient. Encoding may not be necessary on noise-free channels such as VHF FM.

Propagation only becomes a factor as it may take longer for the data to get through during poor conditions. The images received will be identical to the ones sent because the data in the files will also be identical. Replays will always be an exact copy. Multipath propagation does not disrupt DRM transmissions unless it is severe or results in selective fading.

Figure 50 shows an *EasyPal* screen following successful reception of an image.

IMAGE SIZE

Pictures of any size or resolution may be sent over digital SSTV. The sending station must pay careful attention to file size, though, or the transmission time may become excessively long. Compressing image files is necessary to get the transmit time down to a reasonable amount. Most images will be converted into JPEG 2000 (JP2), a lossy compression method that shows fewer artifacts. A slider varies the JP2 compression level, and a compromise must be made between image quality and file size. The smaller the file, the more visible the artifacts, but the

faster it is sent.

Small image files may be sent without using compression. Some file types such as animated GIF files cannot be compressed, so they must be sent "as is."

A "busy picture" is one that shows lots of detail across most of the image area. This type of picture can be challenging to compress into a file size small enough to send that still maintains acceptable quality. Reducing the resolution by resizing and creating a much smaller image is the solution. Just about any busy picture can be resized down to 320×240 pixels, converted into JP2, and still look good when displayed on the receiving end.

About 2 minutes of transmission time is the acceptable limit for the patience of most SSTV operators. A typical HamDRM digital SSTV transmission will take about 105 seconds for a file 23 kB in size, RS1 encoded, and requiring 209 segments.

SENDING DIGITAL SSTV IMAGES

The ideal HamDRM signal will have carriers extending across the 350 to 2750 Hz spectrum. The transceiver should be allowed to pass all frequencies within this bandwidth. In order to maintain the proper phase relationships between all the subcarriers, the signal must be amplified linearly. Avoid overdriving the transmitter and keep the ALC inactive or at the low end of its range. Eliminate hum and other stray signals in the audio.

The process of transmitting an image starts with selecting an image and resizing or compressing it if needed, as described in the previous section. Within EasyPal, when the transmit button is clicked, the image file will be RS encoded if that option is selected. Then the resulting file will be broken down into segments and sent using HamDRM.

In receiving HamDRM, the audio is decoded and segments that pass the error check

will have their data stored in memory. When enough of the segments are successfully received, the RS file is decoded and the JPEG 2000 image file is created. The content of this file should be identical to the JPEG 2000 image file transmitted.

It can be quite gratifying to receive your first digital SSTV picture. A lot has to go just right, and there is little room for error. Propagation and interference can disrupt the signal. There is no substitute for a low-noise location and good antenna when it comes to extracting the image. Help for all aspects of digital SSTV is available on Yahoo Groups DIGSSTV at groups.yahoo.com/groups/ digsstv. Be patient and when the right signal comes by you will see the all the lights turn green and the segment counter will keep climbing resulting in an excellent picture!

10 Glossary of SSTV Terms

ANALOG SSTV TERMS

- AVT Amiga Video Transceiver. 1) Interface and software for use with an Amiga computer; 2) a family of transmission modes first introduced with the AVT product.
- Back porch The blank part of a scan line immediately following the horizontal sync pulse.
- **Chrominance** The color component of a video signal. Robot color modes transmit pixel values as luminance (Y) and chrominance (R-Y [red minus luminance] and B-Y [blue minus luminance]) rather than RGB (red, green, blue).
- Demodulator For SSTV, a device that extracts image and sync information from an audio signal.
- Field Collection of top-to-bottom scan lines. When interlaced, a field does not contain adjacent scan lines and there is more than one field per frame.
- *Frame* One complete scanned image. The Robot 36-second color mode has 240 lines per frame
- *Frame Sequential* A method of color SSTV transmission that sent complete, sequential frames of red, then green and blue. Now obsolete.
- Front porch The blank part of a scan line just before the horizontal sync.
- *Header*—The information preceding the main signal that holds information about the picture. This is essential to successful reception.
- *Interface*—The electronic equipment that connects, or interfaces, your computer to the transceiver.
- Interlace Scan line ordering other than the usual sequential top to bottom. AVT "QRM" mode is the only SSTV mode that uses interlacing.
- *Line Sequential* A method of color SSTV transmission that sends red, green and blue information for each sequential scan line. This approach allows fullcolor images to be viewed during reception.

- *Luminance* The brightness component of a video signal. Usually computed as Y (the luminance signal) = 0.59 G(green) + 0.30 R (red) + 0.11 B (blue).
- **Martin** A family of amateur SSTV transmission modes developed by Martin Emmerson, G3OQD, in England.
- **Pixel** Picture element. The dots that make up images on a computer's monitor.
- **P7 monitor** SSTV display using a CRT having a very-long-persistence phosphor.
- RGB Red, Green, Blue. One of the models used to represent colors. Due to the characteristics of the human eye, most colors can be simulated by various blends of red, green, and blue light.
- **Robot** (1) Abbreviation for Robot 1200C scan converter; (2) a family of SSTV transmission modes introduced with the 1200C.
- **Scan converter** A device that converts one TV image format to another. For example, the Robot 1200C converts SSTV to and from FSTV.
- Scottie A family of amateur SSTV transmission modes developed by Eddie Murphy, GM3SBC, in Scotland.
- **SNR**—Signal-to-Noise Ratio. The higher the SNR, the clearer the received signal.
- **SSTV** Slow Scan Television. Sending still images by means of audio tones using transmission times of a few seconds to a few minutes.
- **Sync** That part of a TV signal that indicates the beginning of a frame (vertical sync) or the beginning of a scan line (horizontal sync).
- VIS Vertical Interval Signaling. Digital encoding of the transmission mode in the vertical sync portion of an SSTV image. This allows the receiver of a picture to automatically select the proper mode. This was introduced as part of the Robot modes and is now used by all SSTV software designers.

- *Waterfall*—This is a representation of the received (or transmitted) signal. It is displayed as a moving image that scrolls downward in the SSTV software as time progresses.
- Wraase A family of amateur SSTV transmission modes first introduced with the Wraase SC-1 scan converter developed by Volker Wraase, DL2RZ, of Wraase Electronik, Germany.

DIGITAL SSTV TERMS

- **Bad segment report (BSR)** A BSR is sent by the receiving station when an image is not received completely. Once the BSR is received a FIX screen is shown allowing the transmitting station to select the picture to fix or simply fix the last image sent. Only bad segments will be resent.
- COFDM Coded Orthogonal Frequency Division Multiplex, a method of using spaced subcarriers that are phased in such a way as to reduce the interference between them, plus coding to provide error correction and noise immunity.
- **Constellation** A set of points in the complex plane that represent the various combinations of phase and amplitude in a QAM or other complex modulation
- Cyclic redundancy check (CRC) —A mathematical operation. The result of the CRC is sent with a transmission block. The receiving station uses the received CRC to check transmitted data integrity to determine if the data received is good or bad.
- Digital Radio Mondiale (DRM) -A system for digital sound broadcasting in bands between 100 kHz and 30 MHz developed by a consortium of broadcasters, manufacturers, research and governmental organizations. Amateurs use a modified version (HamDRM) for sending digital voice and images.

- *Error Protection* DRM submode selection. The HI level provides a greater amount of FEC used within the
- *Fast access channel (FAC)* Auxiliary channel always modulated in 4QAM. Contains the submode and station information.
- **FEC** Forward error correction, an error-control technique in which the transmitted data is sufficiently redundant to permit the receiving station to correct some errors.
- FIX A response to a received BSR. You have the option to FIX an incomplete image that has been received by another station.
- **LeadIn** The number of redundant segments sent at the beginning of the DRM file transmission to allow the receiving station to become synchronized.

- *Main service channel (MSC)* Contains the data. Can be modulated in 4QAM, 16QAM or 64QAM.
- *Mode* In digital SSTV, a particular submode of a DRM transmission. The amount of data in each segment is determined by the submode selected. Robustness varies for each submode.
- **OAM** Quadrature Amplitude Modulation. A method of simultaneous phase and amplitude modulation. The number that precedes it, for example 64QAM, indicates the number of discrete stages in each pulse.
- Reed-Solomon error correction A data encoding process that inserts redundant data so that errors in reading the data may be detected and corrected. EasyPal software provides four levels ranging from Very Light Encode (RS1) to Heavy Encode (RS4).

- **Resolution**—The resolution of an image is the detail of that picture. Higher resolutions result in large image sizes and therefore take longer to transmit but will result in a received image having greater detail.
- **RS Files**—These are encoded files using the Reed Solomon encode/decode protocol.
- Segment A portion of the transmitted image. Many segments make up the total image. Bad segments can be re-sent faster than resending the total image. It contains file name or transport ID and
- **Thumbnail**—This is a miniature view of an image.
- TUNE In DRM, a three-tone transmission used to set levels, check for IMD and adjust frequency.

Station Accessories and Projects

An Amateur Radio station is much more than the transceiver, amplifier and other major pieces of equipment found in a typical ham shack. In this chapter you will find a number of accessory items to make operation more convenient, or to tie other pieces of equipment together. Projects include antenna matching and switching solutions, transceiver/computer interfaces and other station accessories. Additional station accessory projects may be found with the downloadable supplemental content.

1 A 100-W Compact Z-Match Antenna Tuner

A Z-Match tuner will match just about anything on all HF bands, and only uses two controls. They are well regarded, but acquiring the necessary air-wound inductors and variable capacitors can be difficult. In addition, air-wound inductors imply large tuners. The antenna tuner described here by Phil Salas, AD5X, is compact enough for portable HF operation, handles 100 W and uses readily available parts. The Z-Match circuit was originally described in "Multiband Tuning Circuits" by R.W. Johnson, W6MUR, in July 1954 *QST* and the article is included in this book's supplemental material.

The idea for this project came from an article by Charles Lofgren, W6JJZ, in the ARRL Antenna Compendium Vol 5. In that article, the author suggested using a toroid core-based inductor. This would solve the air-core inductor/size problem. Suitable variable capacitors are available at a good price. The result is the compact unit shown in **Figure 1**.

Figure 1 — The Z-Match Tuner handles 100 W and can be used from 80 through 10 meters.

TUNER CONSTRUCTION

The final circuit shown in **Figure 2** is based on W6JJZ's article. The only real change was to go from two switch-selected output links (10 turns and 4 turns) to a single 8-turn output link, and to increase the variable capacitor size to 400-pF. The tuner provides a good match from 80-10 meters!

The tuner is built into a $3 \times 5^{1/4} \times 5^{7/6}$ inch (HWD) aluminum box. Toroid T1 is supported by its leads and some hot glue between the inductor and the frame of C2. Also put a little hot glue between T1 and the side of the case.

The variable capacitors must be insulated from ground, therefore mount both capacitors on a piece of single-sided circuit- or perf-board that is cut just wide enough to fit into the aluminum case. Then mount this capacitor/perf-board assembly in the case with stand-off screws. Capacitor shaft couplings are made from a ½-NPT brass nipple, available from the plumbing section of most hardware stores. These nipples have a ¼-inch inside diameter. Cut a 1-inch nipple in half to make two couplers. Then drill and tap holes for two #6 screws in each piece. See **Figure 3** for capacitor mounting and shaft coupler details. For the insulated shafts, use ¼-inch diameter nylon rods available from many hardware stores.

OPERATION

Tuning the Z-Match tuner is very easy. First adjust C2 for maximum receiver noise. Then apply some RF power and adjust C1 and C2 for minimum SWR. If you need more capacitance for matching, use S1 to switch in the extra section of C1, or switch in a fixed mica capacitor across C1. Balanced feed lines

terminated in banana plugs can plug right into the center pin of the output SO-239 and the adjacent banana jack. To feed coax, ground one end of the output link with switch S2.

OPTICAL HF SWR METER FOR THE Z-MATCH TUNER

While you can use any external SWR meter

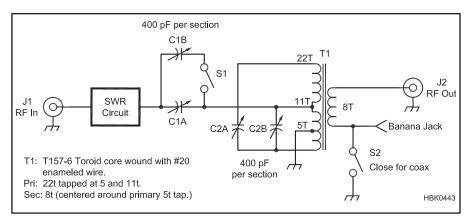

Figure 2 — Schematic of the 100-W Z-Match tuner.

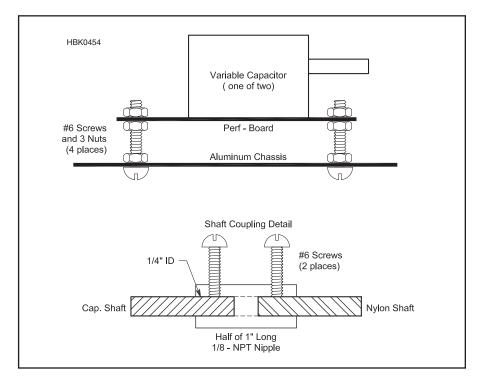

C1, C2 — 400 pF per section, 2-section variable capacitor (Oren Elliott S2-399, www.orenelliottproducts.com). If you substitute another variable capacitor, use one with at least 350 pF per section, rated at 500 V RMS minimum.

J1, J2 — SO-239 connectors.

S1, S2 — SPDT mini-toggle switch.

T1 — Primary: 22 turns #20 AWG enam wire tapped at 5 and 11 turns. Secondary: 8 turns, with 4 turns either side of the primary 5 turn tap. Wound on T157-6 toroid (Amidon Associates, www.amidon-inductive.com).

Enclosure (Eagle, 40UB103 from www. mouser.com).

with the Z-Match tuner — including the SWR meter built into most rigs — the author built an optical SWR meter into the same case for convenience. Refer to **Figure 4A**. It works well with high intensity LEDs rather than conventional meters. The SWR meter is built on a small piece of perf-board and mounted to the solder lug on the tuner's input SO-239. A little hot glue between the perf-board and the back of the chassis adds stability (**Figure 5**).

This broadband circuit works well at the 100-W power level through at least 30 MHz. With careful lead control, it should work up through 6 meters. The transformer is an FT37-43 ferrite core wound with 10 bifilar turns of #26 enameled wire. The primary is just the single wire passing through the center of the toroid. To calibrate the SWR bridge, connect the output to a resistive 50- Ω load. Apply RF power on any HF band and adjust the 20-pF variable capacitor until the REFL LED goes out.

The FWD LED gives an indication of transmitter forward power. You may want to increase the value of the 4.7 k Ω resistor in the FWD circuit if the green LED is too bright. Or you could eliminate this LED and just use the REFL LED.

A BAR-GRAPH DISPLAY FOR THE OPTICAL SWR METER

If you can supply dc power to your Z-Match Tuner and SWR meter, you may want to add the bar graph display as shown in Figure 4B to display SWR reflected power. A version of the tuner with bar graph option is shown in Figure 6 The nice thing about using the bar graph display is that it seems easier to null the reflected power because the display gives more of an analog meter "feel." Adjust the Z-Match tuner for minimum brightness of the REFL LED. When this occurs, the SWR should be less than 1.5:1.

This tuner addresses the issues of inductor size and finding reasonably priced multisection variable capacitors. The result is a wide-band, easily adjustable tuner for either portable or base station operation.

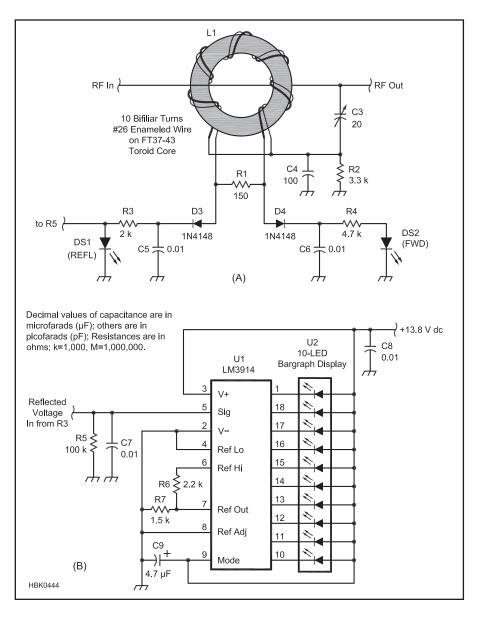

Figure 3 — The variable capacitors are insulated from the chassis by mounting them on perforated board. A 1/8-NPT nipple is made into a shaft coupling to couple the insulating shafts to the main capacitor shafts.

Figure 4 — Optical SWR meter schematic with the bar graph display modification (see text). The basic LED version is shown in A and the bar graph addition in B. C3 — 2-20 pF variable capacitor (Mouser 24AA113 4-34 pF variable is suitable).

D1 — Red LED, high-intensity.

D2 — Green LED, high-intensity.
L1 — 10 bifilar turns of #26 enam wire on FT37-43 toroid core (Amidon Associates, www.amidon-inductive. com).

U1 — Display driver IC, LM3914 (All Electronics, www.allelectronics.com).
U2 — 10-LED bar graph display (Mouser 859-LTL-1000HR). Any 10-segment LED bar graph will work, but verify pinout.

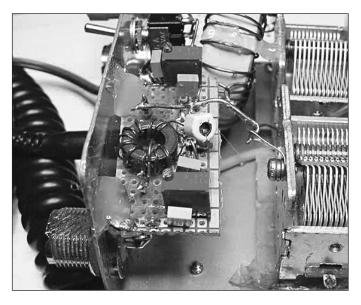

Figure 5 — The SWR meter circuit board is soldered directly to the RF input connector and attached to the back panel with hot glue.

Figure 6 — The bar graph display of reflected power makes tuning easier and more intuitive.

2 A Microprocessor Controlled SWR Monitor

This update of the basic SWR meter, designed by Larry Coyle, K1QW, uses a microprocessor to drive an analog panel meter, exploiting the best features of both analog and digital technology. The instrument also displays forward/reflected/net power and return loss (see the **Transmission Lines** chapter) with peak-hold capability. All display selections are selected by front panel switches. [More information is available on K1QW's Web site, www.lcbsystems.com, and a complete package of information on this project with supporting files and photos is available with the downloadable supplemental content.]

OVERVIEW AND BLOCK DIAGRAM

After a bit of work, the author came up with the SWR/Power/Return Loss monitor shown in block diagram form in Figure 7. There are three interacting assemblies: SWR sense head, front panel assembly and signal processor board. (The latter two make up the Display and Signal Processor unit.) The SWR sense head is a conventional Stockton dual-transformer bridge with Schottky diode detectors. This component converts the forward and reflected RF amplitudes to dc and connects to the Display and Signal Processor by an ordinary stereo audio cable.

The user interface to the SWR monitor is familiar and intuitive. As you can see in **Figure 8A**, a front-panel rotary switch selects the quantity to be measured and an analog meter displays the result.

- •Forward power on a linear scale
- •Reflected power as a percentage of forward power
- RF in (50Ω coax)
 SWR sense head
 stereo audio cable
 Display and Signal Processor Unit
 HBK0623

Figure 7 — This block diagram shows how the SWR sense head and the signal processor box are connected by an ordinary two-conductor shielded stereo audio cable. The signal processor box contains the processor board and the front panel assembly.

- •Net power delivered to the load
- •SWR on a linear scale
- •Return loss on a linear scale Some additional features are:
 - Peak-hold front panel switch
- A front panel switch to multiply the meter sensitivity by 3X
- •Data logging to a computer using the USB port.
- •Transmitter Lockout (XLO) at high SWR The rear panel, **Figure 8B**, shows the power switch and external connections

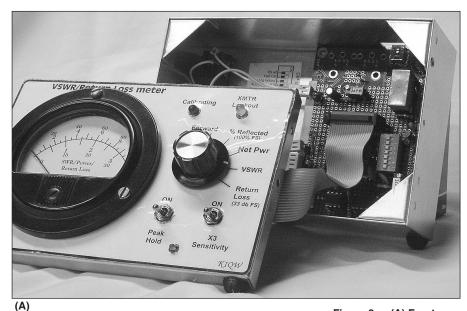

Transmitter Lockout (XLO) is a protective feature that lights a LED on the front panel and energizes a relay when the SWR exceeds a preset level. This opens a set of relay contacts which are connected to a pair of banana jacks on the rear panel. Once triggered, the relay remains energized for either three or nine seconds, depending on the configuration of the DIP switch located on the signal processor

board. The same DIP switch also allows you to select the SWR level at which the XLO relay triggers — 1.5, 2, 3 or 4:1. By connecting the relay contacts in series with your rig's PTT or keying line, transmitting into high SWR can be prevented.

The two dc signals from the sense head make up the analog input to the signal processor board. The analog output for driving the meter is a pulse width modulated (PWM) signal generated by the microprocessor and smoothed by a simple resistor-capacitor (RC) filter.

THE MICROPROCESSOR

The Parallax "Propeller" microprocessor (www.parallax.com) is unique in that it's really eight processors ("cogs") in one package, each one able to run its own separate program during its own time slot, controlled by a central "hub." This may sound challenging, but

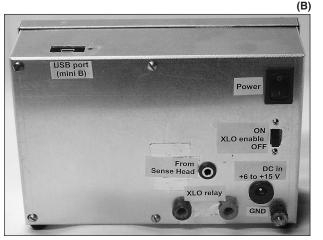

Figure 8 — (A) Front panel of the display and signal processor unit. The meter face and the front panel lettering were created using Microsoft Visio, printed on heavy paper stock and attached with contact cement. With the front cover moved aside, you can see the ribbon cable carrying signals between the front panel assembly and the processor board. (B) Rear panel of the display and signal processor. The mini-B USB connector is accessible through the opening on the top surface of the enclosure.

this actually makes programming the chip much easier. If you need to carry out several tasks at once — and most microprocessor applications do — just assign each job to its own individual cog and work on them separately. The central hub makes sure each cog gets its turn and keeps things synchronized.

The project uses the 3 × 4 inch Propeller USB Development Board from Parallax. It includes the Propeller chip, an Electrically-Erasable Programmable Read-Only Memory (EEPROM) for program storage, a 5 MHz crystal, two voltage regulators and, a USB mini-B connector with all the necessary USB interface circuitry.

The Propeller is programmed in a language called "Spin" which should make anyone who is familiar with the BASIC computer language feel at home. All the tools you need to write software for and to program the Propeller is available for free on the Parallax Web site, including an extensive library of pre-built code routines that you can just drop into your own programs.

Software is loaded onto the development board using the USB port from a host computer with a USB port. When not in use as a programming port, the same USB port is used as a serial data port for passing data between the SWR monitor and a computer running a terminal program such as HyperTerminal.

MICROPROCESSOR BOARD CIRCUITRY

The development board includes a prototyping area large enough to hold all the parts of the SWR monitor except for front and rear panel components. Since most of the parts come assembled on the development board, construction of the digital board is quite easy. As you can see in **Figure 9A**, the electrical schematic, only two integrated circuits and a few analog components are required.

The dc signals representing forward and reflected power from the SWR sense head are received by dual op-amp U2. Each section of U2 is configured as a unity-gain voltage follower with a compensating diode (D1 and D2) to balance out the dc offset introduced by the Schottky rectifier diodes in the sensing head. (The technique of using a diode in the feedback path of an op amp to compensate for the non-linearity of an RF detector diode is described in detail in "A Compensated, Modular RF Voltmeter" in the Test Equipment and Measurements chapter of this book.) Each section also has an RC low-pass filter at its input to filter out unwanted RF — always a possibility around a ham shack.

The next stage in the signal path is U3, an analog multiplexer (MUX). This chip acts as a three-position switch under control of the microprocessor. (A fourth channel is unused.) The forward and reflected signals (on pins 14 and 15) are sampled alternately, 20 times per

second, as long as the program is running. The third input to the MUX (pin 12) is grounded, and is also sampled by the microprocessor from time to time. This gives a measure of any dc offsets introduced by the analog-to-digital conversion and is used to correct the forward and reflected readings in software. This automatic zero adjustment takes place every five seconds or so and is indicated by a brief flash from the front-panel "Calibrating" LED that also serves as a "digital heartbeat" to show that the software is running.

The MUX output (pin 13) is passed to a potentiometer voltage divider to allow the scale factor to be set during calibration. From there it goes to the Propeller microprocessor itself where a delta-sigma analog-to-digital conversion takes place.

DIGITAL INPUT/OUTPUT

The microprocessor responds to the user's inputs by monitoring the state of 13 digital input pins. Most of these pins are controlled by the rotary and toggle switches on the front panel. The panel connects to the processor board by a short ribbon cable as shown in Figure 8A. See Figure 9B for a schematic of the separate front panel assembly. The ribbon cable also carries power for the LEDs.

On the processor board there are a multisection dual in-line package (DIP) switch, S2, and two jumpers, JP1 and JP2, which select among the various operating modes. Lastly, the Xmtr Lockout (XLO) switch is mounted on the rear panel and visible in Figure 8B. These inputs to the microprocessor and the various modes of operation they control are summarized in Table 1A. The digital inputs are all active low; ie, the function is enabled when the signal line is at a low logic level. XLTHRESH1 and XLTHRESH0 form a twobit code to select one of four SWR levels. When this SWR level is exceeded and if XLO is enabled, the transmitter lockout function is triggered.

There are only six digital *outputs*:

- •Two address lines for the analog MUX to select among the three input channels
- •Two lines to power the Calibrating and XLO LEDs located on the front panel
- •One PWM signal to drive the front-panel analog meter
 - •One line to control the XLO relay.

Figure 8A shows the built-up processor board inside the $2 \times 4 \times 6$ inch aluminum enclosure connected to the front panel with the ribbon cable. Here you can also see some of the wiring to the rear panel components. The USB connector is at the top edge of the circuit board and is accessible through a rectangular hole nibbled out of the top surface of the aluminum box.

THE RF SENSE HEAD

The SWR sense head is the business end of the SWR meter where the forward and reflected amplitude components of the RF present on the transmission line are separated and converted to dc. For this project I adopted a straightforward Stockton directional

coupler circuit, with Schottky diode detectors and, unlike other designs, it requires no balancing trimmers. The schematic is given in **Figure 10** and the circuit is described in the article by J. Grebenkemper, KA3BLO, "The Tandem Match — an Accurate Directional Wattmeter," *QST*, Jan 1987, pp 18-26 (also published in the 2009 and earlier editions of *The ARRL Handbook*).

The accuracy of this circuit can be greatly improved by taking care to match the diodes in the sensing head with the corresponding compensation diodes in the op ampinput stages on the signal processor board (D1 and D2 in Figure 9A). The easiest way to do this is with the diode test function included on most utility digital multimeters which passes a small dc current through the diode being tested and displays the forward voltage drop. The high-frequency range can be extended by using surface-mount components in the sensing head.

There are two versions of the SWR sensing head. The QRP version has a maximum range of 10 W. The other can handle up to 100 W. The only difference between the two versions is the number of turns on the toroid transformers (see the parts list in Figure 10). The high frequency performance of the 100-W head at

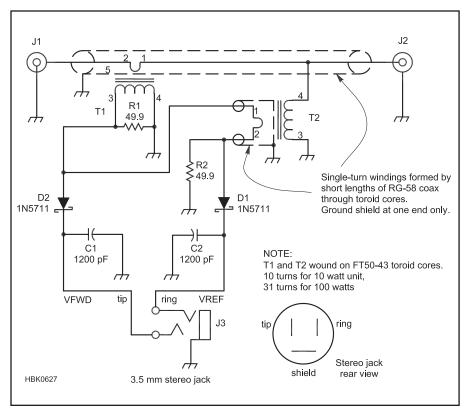

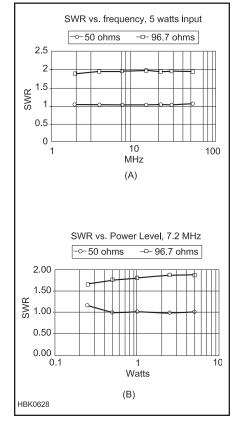

Figure 10 — SWR sense head schematic. All components except for the transformers are surface mount parts. R1 and R2 are size 1210, rated at $\frac{1}{2}$ W. Transformers T1 and T2 are wound on FT50-43 ferrite toroid cores. For the 10-W sense head, use 10 turns of 24 AWG wire. For the 100-W head, use 31 turns.

50 MHz proved to be poorer than the 10-W unit. I attribute this to the added capacitance of the transformer windings (the higher power transformers have three times as many turns as the low-power ones).

The overall accuracy of the monitor compares fairly well to commercial devices. **Figure 11A** and **11B** show performance data I took using dummy loads of 50 and 96.7 Ω . At five watts input, using the 10-W sensing head, the SWR readings were within 3% over a range of 1.8 to 30 MHz, and within 5% at 50 MHz. Figure 11B shows good accuracy down to 500 mW input (great for QRP rigs!) and is even usable down to 250 mW.

velopment Board, is available in the package of supporting files with the downloadable supplemental content. There are also details of the subroutines handled by each of the Propeller cogs plus additional text and graphic files covering operation and features of the instrument.

As explained above, the organization of the Propeller into several peripheral processors (cogs) makes it easy to follow the program flow. The main program object (MAIN) runs in its own cog and is the first to be executed when power is applied (or whenever the chip is reset). Its first order of business is to set individual microprocessor pins to be inputs or outputs, as required.

Next, MAIN starts up three separate cogs for (1) analog-to-digital conversion (the ADC3CHcog), (2) generating the pulse width modulated waveform to drive the analog panel meter (the PWM cog) and (3) communicating with the terminal via the USB port (the MONITOR cog). They run continuously, swapping data with the MAIN program by means of variables stored in memory. After these three cogs are started, the MAIN program object enters a loop, endlessly repeating the following steps:

- 1) Read forward and reflected amplitudes and SWR data generated by the ADC3CH object.
 - 2) Calculate forward power, percent re-

flected power, net power, SWR and return loss in decibels.

- 3) Display the quantity selected by the front panel switch on the panel meter using the PWM object.
- 4) Convert power levels, SWR and return loss information to ASCII strings and send them to the MONITOR object, which writes to the USB port.

This is a shining example of building on the accomplishments of others who have made their work freely available. Without such an extensive library of pre-tested routines on hand, the author probably would never have even started this project.

3 A 160- and 80-Meter Matching Network for Your 43-Foot Vertical

Many amateurs are using 43-ft vertical antennas for multiband operation. These antennas have higher radiation resistance than shorter verticals, which minimizes ground losses. This is especially important when you have an electrically short antenna — a characteristic of even a 43-ft antenna on 160 and 80 meters.

When fed with a 1:4 unun (unbalanced-tounbalanced transformer), a 43-ft antenna has a reasonable compromise SWR on 60-10 meters, which means that cable and unun losses are pretty much negligible on these bands. Performance on 160 meters, and to a lesser extent on 80 meters, is not as good unless you provide matching right at the antenna. The high capacitive reactance and low radiation resistance of a 43-ft antenna on 160 and 80 meters make the mismatch so bad that it is almost impossible to match from your shack if you are using low-loss coax. If you can match the antenna system from your shack, you will lose a lot of power in your coax and unun because of the very bad mismatch at the antenna. Phil Salas, AD5X, describes two impedance matching devices for use with 43-ft verticals designed to significantly reduce SWR-related losses and to "help out" inside tuners on 160 and 80 meters.

THE MATCHING REQUIREMENT

Antenna analyzer measurements of the author's 43-ft vertical antenna indicate a capacitive reactance of about 580 Ω on 160 meters. This value will vary with different kinds of 43-ft verticals, proximity to other objects and other factors unique to each installation but is usually in the 550-650 Ω range. With this amount of capacitive reactance, approximately 50 μH of inductance is

needed to resonate the antenna. On 80 meters, approximately 9 μ H is needed. A 50 μ H high-Q inductor is large, but a toroidal inductor will be more compact.

Figure 12 shows the circuit of a compact design that handles 1500 W SSB or CW on 80 and 160 meters. **Table 2** lists the necessary parts. The inductor consists of 35 turns of #14 AWG solid copper insulated house wiring wound on a T400A-2 toroid core, with the feed tapped 2 turns from the ground end for 80 meters, and 3 turns from the ground end for 160 meters. Start with 38 turns and then remove turns as necessary to get the network to resonate where you want it in the 160 meter band (more on this later).

The toroid assembly fits in a $6 \times 6 \times 4$ -inch NEMA enclosure. The assembly is secured with a 2.5-inch long #10 screw and associated hardware along with a 2×4 inch piece of unplated fiberglass PC board material (**Figure 13**). Before mounting the toroid, prepare it by scraping the insulation off the outside of the wire at turns 2, 3 and 11-13. Because of the high voltages possible with 1500 W (especially on 160 meters), wrap

the toroid with two layers of 3M #27 glasscloth electrical tape for added insulation between the wire and the toroid core.

To select between 160- and 80-meter operation, the appropriate connections are made with external jumpers across binding

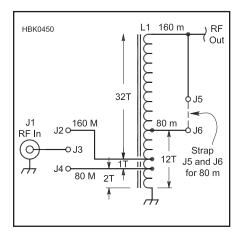

Figure 12 — 160/80-meter impedance matching network for use with a 43-ft vertical. See Table 2 for a parts list.

posts as shown in **Figure 14**. Stainless steel #8 hardware (screws, washers, lockwashers, nuts) is used for the matching unit ground and RF output. Internal to the matching unit, a 2-inch-wide strip of aluminum duct repair tape makes a good low-impedance ground between the coax connector and the ground screw on the bottom of the case. Finally, use #14 AWG stranded insulated wire for all internal connections.

TUNING THE MATCHING NETWORK TO RESONANCE

Your particular installation will almost certainly require you to change the resonant frequency of the matching network. This is because there will be variations of the antenna impedance based on your particular installation and desired operating frequency range. The design is such that the overall inductance is too large for 160 meters, so the network should resonate at or below the lower band edge. Therefore, you will need to remove one or more of the upper inductor turns to resonate the network for the desired frequency on 160 meters. To do this, first solder wires from the turn 2 and 3 tap points on the coil to the two outer binding posts by the RF IN connector. The input tap points tend to be fairly non-critical and will probably always be the same for all installations.

Now solder a short wire from the RF IN center pin to the middle binding post. Next, externally jumper the middle binding post to the 160 meter binding post (turn 3). Connect the matching assembly to the base of your

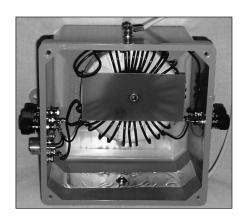

Figure 13 — Mounting details of the toroidal inductor for the 160/80-meters matching unit. The input side of the enclosure is on the left. Coax to the station connects to the RF IN SO-239, and a strap between the center binding post and one of the outer posts selects the input tap for operation on 160 or 80 meters. On the right side, a jumper between the two binding posts shorts a section of the coil for 80-meter operation. The RF OUT connection to the base of the antenna is made with via the #8 machine screw and hardware at the top, and the ground connection is on the bottom.

43-ft vertical and use an antenna analyzer to find the minimum SWR point on 160 meters. If the resonant frequency is too low, remove a turn of wire and measure again. You should see a 50 kHz upward move in frequency per turn of wire removed.

When you have reached the desired resonant point on 160 meters, it is time to move to 80 meters. Externally jumper the input tap middle binding post to the 80-meter binding post (turn 2), and use a clip lead to short from the top of the coil to about turn 12. Again, find the frequency where minimum SWR occurs. Move the tap point up or down until you reach the desired resonance point. Solder a wire from this tap point to one of the binding posts. Solder another wire from the top of the coil to another binding post. Now you will be able to externally jumper these binding posts to go from 160 to 80 meters.

Figure 15 shows the author's final results for 160 and 80 meters as measured with an antenna analyzer connected directly to the matching network input at the base of the antenna. With resonance set for the CW end of these bands, the 2:1 SWR bandwidth on 160 meters is about 50 kHz and about 150 kHz on 80 meters. Even a 3:1 SWR on

(A)

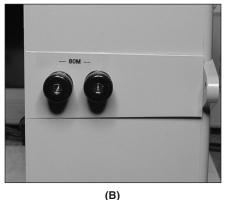

Figure 14 — Binding posts are used for jumpers to select 160 or 80 meter operation.

these bands results in negligible SWR-related cable losses and is easily matched with an in-shack tuner.

OPERATION

Using the matching unit is simple. Just disconnect your normal unun when you want to operate on 160 or 80 meters and connect this matching unit to the base of the antenna. Select either 160 or 80 meters with the external straps. You can connect both the unun and this matching unit to the antenna at the same time, and just leave off the ground wire from the unit that is not used. The matching unit connected to the base of a 43-ft vertical is shown in **Figure 16**.

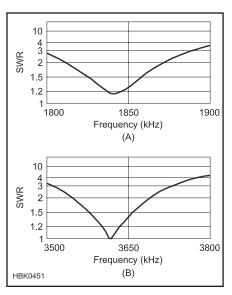

Figure 15 — Measured at the antenna base, the 2:1 SWR bandwidth is about 50 kHz for 160 meters and 150 kHz for 80 meters.

Figure 16 — The finished matching unit at the base of the author's 43-ft antenna (strapped for 80 meter operation).

4 Switching the Matching Network for Your 43-Foot Vertical

Another project in this chapter describes a simple 160 and 80 meter impedance matching network for installation at the base of a 43-ft vertical antenna. While that unit is very effective and inexpensive to build, it is also a little inconvenient in that you must connect it when it is needed, and you must also manually enable 160 or 80 meter operation using jumpers. Phil Salas, AD5X, enhances the original design with a more versatile matching assembly that can be controlled remotely for operation on all bands.

FIRST — A WORD ABOUT RF VOLTAGES

This unit uses relays for selecting the different bands, so a discussion of RF voltages is appropriate. RF voltages at the base of an untuned vertical can be quite high. As the antenna becomes shorter, the capacitive reactance becomes higher and so the resultant voltage drop across the combination of reactance and radiation resistance increases. With the 43-ft vertical, the worst-case situation will occur on 160 meters where the capacitive reactance is approximately 600Ω . The radiation resistance is approximately 3Ω .

With a perfect ground (no ground loss) and 1500 W of power properly matched to the antenna, peak RF voltage works out to about $19,000 \, V_{nk}$:

$$\begin{split} I &= \sqrt{1500 \text{ W} / 3 \Omega} = 22.4 \text{ A} \\ \left| Z \right| &= \sqrt{3^2 + 600^2} = 600 \Omega \\ V_{RMS} &= 22.4 \times 600 = 13,440 \text{ V} \\ V_{pk} &= 13,440 \times 1.414 = 19,004 \text{ V} \end{split}$$

Very few hams have a ground system that is lossless. With a ground loss of $10\,\Omega$ (better than most hams have), it works out to about $9100\,V_{pk}.$ With the author's 600-W amplifier, assuming a ground loss of $10\,\Omega,$ it's about $5800\,V_{nk}.$

The author experimented with two different relays from Array Solutions. The RF-10 DPDT relay has 1.7 kV_{pk} contact-tocontact and 3.1 kV_{pk} contact-to-coil voltage breakdown ratings. This relay proved to be a good solution for up to about 500 W on 160 meters when the two sets of contacts are put in series. The second relay is the RF-3PDT-15 which has 3.1 kV_{pk} contactto-contact and 5.3 kV_{pk} contact-to-coil voltage breakdown ratings. This relay has nearly twice the contact breakdown rating of the RF-10, and it's 3PDT so an additional set of contacts can be put in series to increase the breakdown voltage. This relay can be used in a full legal limit application if applied properly in the circuit (more on this later).

Depending on your power level and ground losses, the less expensive and smaller RF-10 may be all you need. Make the calculations to determine which relay is more appropriate for you. If you look for alternative relays, pay attention to the breakdown voltage rating; it's hard to find relays with suitable ratings for this application. The Array Solutions relays have 30 A contacts, but 15 A or more should be sufficient.

THE ALL-BAND MATCHING SOLUTION

As explained in the companion project describing a simple matching network, when fed with a 1:4 unun (unbalanced-to-unbalanced transformer), a 43-ft antenna has a reasonable compromise SWR on 60-10 meters. The antenna requires approximately 50 µH of inductance to resonate on 160 meters and

 $9~\mu H$ on 80~meters. For convenient all-band operation from the shack, the solution shown in **Figure 17** uses two relays to switch in the unun for 60-10~meter operation or the appropriate inductance for 160~and~80~meters. The unit will handle up to 1500~W~from~160-10~meters.

Relay control requires inputs of 0 V, +12 V dc or -12 V dc. The matching unit operates as follows:

- •With no control voltage applied, the 1:4 unun is connected to the antenna for 60-10 meter operation, and the inductor is disconnected, so the original antenna compromise SWR on these bands is preserved.
- •With +12 V applied for 80-meter operation, K1 and K2 close. Contact K1C connects the unun secondary to L1 through K2C at the 200 Ω point (6 turns from the ground end). Contacts K2A and K2B short out the top part

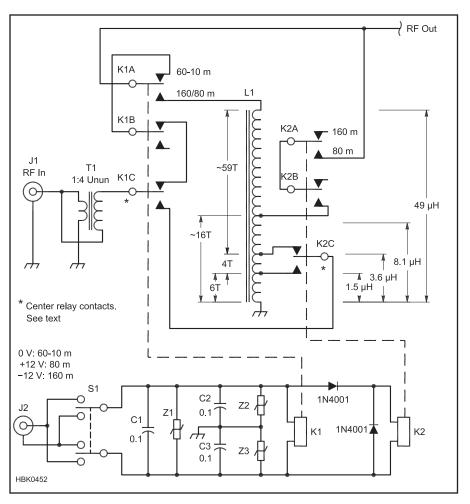

Figure 17 — This switched impedance matching network for use with a 43-ft vertical allows operation on 160-10 meters and is controlled from the station operating position. See Table 3 for a parts list.

of L1 (about 16 turns from the ground end), resonating the antenna on 80 meters.

•When the voltage is reversed (-12~V) for 160-meter operation, K1 stays closed but K2 opens. K2C now connects the unun secondary to L1 at the 200 Ω point for 160 meters (10 turns from the ground end). Contacts K2A and K2B open, removing the short and allowing the entire coil to be used to resonate the antenna on 160 meters.

Connecting the unun to L1 at the 200 Ω point keeps the unun secondary voltage reasonable, and the feed line and unun losses very low as well.

CONSTRUCTION

Figure 18 shows the layout. The matching unit is built in $8 \times 8 \times 4$ -inch NEMA weatherproof box available from most home centers. The author used an MFJ 404-0669 airwound coil, and this box is too small to fit the entire inductor length needed. The inductor is split into two pieces; the long section consists of 61 turns, and the short section consists of 12 turns. As drawn in the schematic, the longer coil section is at the "bottom" (one end connects to ground), while the shorter coil is at the "top" (one end connects to RF OUT). If you have room for a larger box, a 12×12

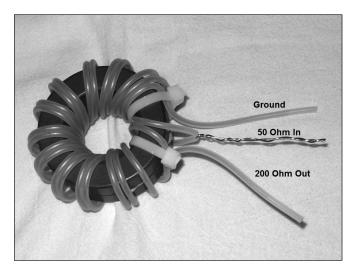

Figure 19 — Connections for a voltage unun (MFJ 10-10989D shown).

× 4-inch NEMA box fits the full inductor length without cutting.

Two Array Solutions RF-3PDT-15 relays are mounted to the case next to each other in the upper center. These are enclosed relays with all connections on one side, making for easy assembly. The 2.1×5.5 mm dc power jack and SO-239 RF IN connector are in the upper left corner. The MOVs and bypass capacitors for the control line are mounted on a terminal strip near the power connector.

The unun is mounted to the side of the enclosure using a machine screw and a piece of PC board material with the copper removed. The antenna is unbalanced, so a current balun or voltage unun (*not* a voltage balun) is typically used. A voltage unun should be wired as shown in **Figure 19**.

All internal wiring consists of insulated #14 AWG stranded wire. Attach the wires to the coil tap points using the MFJ coil clips called out in the parts list. (You can solder the

wires directly to the coil, but this is difficult because of the size of the coil wire and the spacing of the turns.) Use #8 stainless steel screws, washers, lock-washers and nuts for coil mounting, and for the ground and RF OUT (antenna feed) terminals. **Table 3** lists the parts and part sources.

Relay Connections

As discussed earlier, the voltage across the full coil can be very high on 160 meters. Connecting the relay contacts in series as shown in the schematic increases the overall breakdown voltage. Also, the tap points on the inductor provide additional voltageabove-ground, which helps with the overall breakdown voltage.

The main concern is with the contact-tocoil breakdown rating of 5.3 kV peak. The

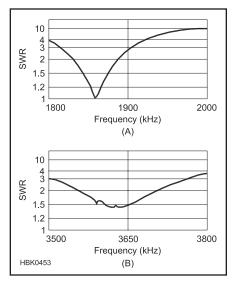

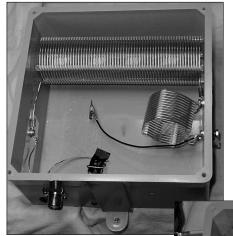

Figure 20 — Measured at the antenna base, the 2:1 SWR bandwidth is about 50 kHz for 160 meters and 150 kHz for 80 meters.

(A)

Figure 18 — Inside the enclosure. At A, the airwound inductor has been cut into two pieces (see text) and mounted. The wire from the shorter piece will attach to the RF OUT terminal. At B, the other components have been added. The unun is mounted on the left side of the case. The relays are at the top center, and the MOVs and bypass capacitors are mounted on a terminal strip at the upper left, next to the RF IN and dc control

connectors.

outer contacts are connected via insulated internal wires that are well separated from the coil by 0.1-0.2 inch. The problem is with the common wire for the center contacts, which is in contact with the coil. While the coil and common wire are both insulated, there is no air gap separation between them; this close proximity is what determines the relay breakdown voltage rating. Wired as shown in Figure 17, the center relay contacts are used for the lowest voltage points.

Misc: #14 AWG house wiring, stainless steel hardware.

The switched control voltage input uses

a 12-V, 1-A wall transformer supply. It's a good idea to keep the ± 12 V control voltages separate and isolated from the regular station power supply to eliminate any possibility of shorting the main power supply when the control voltage polarity is flipped. The switching is easily done with a DPDT center-off switch (S1).

MATCHING NETWORK RESONANCE

Some initial adjustment is required to tune the resonant frequency of the match-

> ing network to account for variations in the antenna impedance based on your particular installation and desired operating frequency range. The overall starting inductance is too large for 160 meters, so the network will resonate at or below the lower band edge. Therefore, you can simply short one or more turns at the upper (RF OUT) end of the inductor to tune the network higher in frequency.

For the initial adjustments, don't connect the wire leads that attach between the relay contacts and the tap points on the coil. Instead, build short jumpers using the test clips and micro clips (perfect for the coil turn taps) called out in the parts list, and attach these between the relay contacts and coil using the suggested tap points shown on the schematic.

Next, connect the matching assembly to the base of your 43-ft vertical, enable 160 meter operation by applying –12 V dc and jumper turns from the RFOUT end of the inductor with a short clip lead until you find the desired 160 meter resonance point. Next, move the 160 meter relay tap point (from the unun secondary through K2C) until you get minimum SWR. (The starting point is 10 turns from the ground end.) Now permanently short the inductor turns by soldering a piece of #16 AWG buss wire across them. As shown in the photos, the author needed to short six turns (on the short coil).

Next apply +12 V to the relay assembly to enable 80-meter operation. Select the coil shorting point (from K2B — start 16 turns from the ground end) for your desired resonant frequency. Then adjust the tap point (from K2C — start 6 turns from ground) for best SWR. Finally remove the test clips leads, attach the coil clips, and solder wires between the coil clips and relay.

Figure 20 shows the results for 160 and 80 meters as measured with an antenna analyzer connected directly to the matching network input at the base of the author's antenna. With resonance set for the CW end of these bands, the 2:1 SWR bandwidth on 160 meters is about 50 kHz and about 150 kHz on 80 meters. Even a 3:1 SWR on these bands results in negligible SWR-related cable losses and is easily matched with an in-shack tuner.

OPERATION

Operation of this matching unit couldn't be simpler. When no control voltage is applied, the unun is connected and the antenna functions as it always has on 60-10 meters. For 80-meter operation, apply +12 V dc, and for 160-meter operation apply -12 V dc. The matching unit connected to the base of the author's 43-ft vertical is shown in **Figure 21**.

The matching network discussed in this article will permit very effective operation of your 43-ft vertical on all bands from 160-10 meters. Feel free to experiment a little. You might prefer to use the toroid from the basic matching network in the companion project instead of the air-core inductor. And if you are not running more than about 500 W, the less expensive RF-10 relays are all you need.

Figure 21 — The switchable matching unit mounted at the base of the author's 43-ft vertical.

5 An External Automatic Antenna Switch for Use With Yaesu or ICOM Radios

This antenna-switching-control project involves a combination of ideas from several earlier published articles. 1,2,3 This system was designed to mount the antenna relay box outside the shack, such as on a tower. With this arrangement, only a single antenna feed line needs to be brought into the shack. Figure 22 shows the control unit and relay box, designed and built by Joe Carcia, NJ1Q. Either an ICOM or Yaesu HF radio will automatically select the proper antenna. In addition, a manual switch can override the ICOM automatic selection. That feature also provides a way to use the antenna with other radios. The antenna switch is not a two-radio switch, though. It will only work with one radio at a time.

Many builders may want to use only the ICOM or only the Yaesu portion of the interface circuitry, depending on the brand of radio they own. The project is a "hacker's dream." It can be built in a variety of forms, with the only limitations being the builder's imagination.

CIRCUIT DESCRIPTION

Figure 23 is a block diagram of the complete system. An ICOM or Yaesu HF radio connects to the appropriate decoder via the accessory connector on the back of the radio. Some other modern rigs have an accessory connector used for automatic bandswitching of amplifiers, tuners and other equipment. For example, Ten-Tec radios apply a 10 to 14-V dc signal to pins on the DB-25 interface connector for the various bands. Other radios use particular voltages on one of the accessoryconnector pins to indicate the selected band. Check the owner's manual of your radio for specific information, or contact the manufacturer's service department for more details. You may be able to adapt the ideas presented in this project for use with other radios.

A single length of coax and a multiconduc-

tor control cable run from the rig and decoder/control box to the remotely located switch unit. The remote relay box is equipped with SO-239 connectors for the input as well as the output to each antenna. You can use any type of connectors, though.

ICOM radios use an 8-V reference and a voltage divider system to provide a stepped band-data output voltage. **Table 4** shows the output voltage at the accessory socket when

the radio is switched to the various bands. Notice that seven voltage steps can be used to select different antennas. The ICOM accessory connector pin assignments needed for this project are:

Pin 1	+8 V reference
Pin 2	Ground
Pin 4	Band signal voltage
Pin 7	+12 (13.8) V supply
Yaesu radios pro	vide the band information

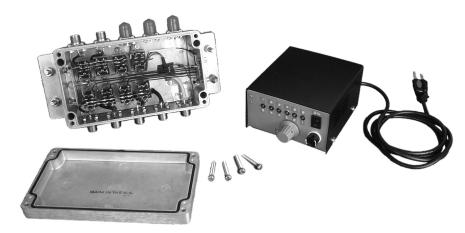

Figure 22 — Automatic antenna switch relay box (left) and control box (right).

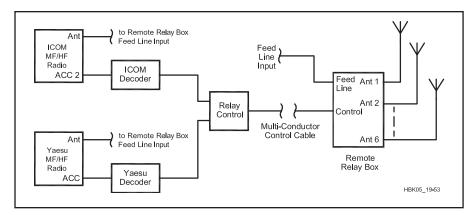

Figure 23 — Block diagram of the remotely controlled automatic antenna switch.

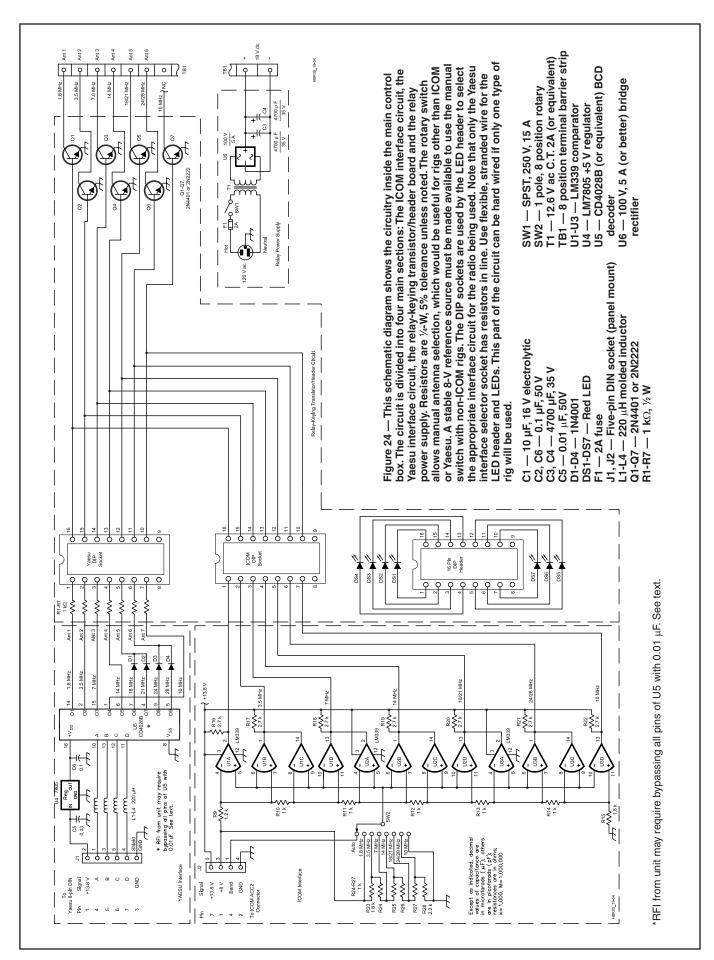

Table 4 ICOM Accessory Connector Output Voltages By Band

Band (MHz)	Output Voltage
1.8	7 - 8.0
3.5	6 - 6.5
7	5 – 5.5
14	4 - 4.5
18, 21	3 - 3.5
24, 28	2 - 2.5
10	0 - 1.2

Note: The voltage step between bands is not constant, but close to 1.0 V, and the 10-MHz band is not in sequence with the others.

Table 5 Yaesu Band Data Voltage Output (BCD)

		_		,	
Band	Α	В	C	D	(BCD Equiv.)
	(1)	(2)	(4)	(8)	
1.8	5V	٥V	OV	٥V	1
3.5	0V	5V	OV	0V	2
7.0	5V	5V	OV	0V	3
10.1	OV	OV	5V	0V	4
14	5V	OV	5V	0V	5
18.068	OV	5V	5V	0V	6
21	5V	5V	5V	0V	7
24.89	OV	OV	OV	5V	8
28	5V	OV	OV	5V	9

as binary coded decimal (BCD) data on four lines. Nine different BCD values allow you to select a different antenna for each of the MF/HF bands. Table 5 shows the BCD data from Yaesu radios for the various bands. The Yaesu 8-pin DIN accessory connector pin assignments needed for this project are:

+12 (13.8) V supply Pin 1

Pin 3 Ground

Pin 4 Band Data A

Pin 5 Band Data B

Band Data C Pin 6

Band Data D Pin 7

Figure 24 is the schematic diagram for the control box. We will discuss each part of the control circuit later in this description. First, let's turn our attention to the external antenna box.

EXTERNAL ANTENNA BOX

Only the number of control lines going out to the relay box limits the number of antennas this relay box will switch. The unit shown in the photos has 10 SO-239 connectors, to switch the common feed line to any of nine antennas. Many hams will use an eight-conductor rotator cable (such as Belden 9405) to the relay box. Using eight wires, we can control seven relays (six for antennas and one to ground the feed line for lightning protection) plus the relay coil power supply and ground lead. The photos show eight relays, and the box can be expanded further if desired. There is also a connector for power and control lines. Use of a DB-15 allows for the addition of more relays and control lines later. A DB-9 connector would be suitable for use with the eight-conductor control cable, or you may wish to use a weatherproof connector. Figure 25 shows the relay box schematic diagram.

Since the box will be located outside, use a weatherproof metal box — a Hammond Manufacturing, type 1590Z150, watertight aluminum box is shown. It's about $8.5 \times 4.25 \times 3.125$ inches. This is a rather hefty box, meant to be exposed to years of various weather conditions. You can, however, use almost anything.

The coax connectors are mounted so each particular antenna connector is close to the relay, without too much crowding. For added weather protection (and conductivity), apply Penetrox to the connector flange mount, including the threads of the mounting screws. On the power/control line connector, use Coax Seal or other flexible cable sealant.

The aluminum angle stock on either side of the box is for mounting to a tower leg. The U-bolts should be of the proper size to fit the tower leg. They should also be galvanized or made of stainless steel.

ANTENNA RELAYS

One of the more difficult parts of this project was the modification of the relays (DPDT Omron LY2F-DC12). To improve isolation, the moveable contacts (armature) are wired in parallel and the connecting wire is routed through a hole in the relay case.

Remove the relay from its plastic case. Unsolder and remove the small wires from the armatures. Carefully solder a jumper across

the armature lugs with #20 solid copper. Then solder a piece of very flexible wire (such as braid from RG-58 cable) to either armature lug. Obviously, the location of the wire depends on which side you wish to connect the SO-239. You will also need to make a hole in the plastic case that is large enough to accommodate the armature wire without placing any strain on the free movement of the armature. Slip a length of insulating tubing

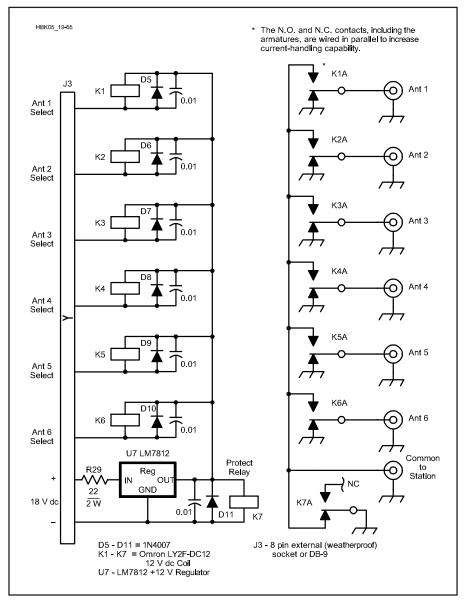

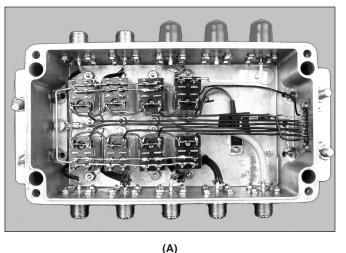

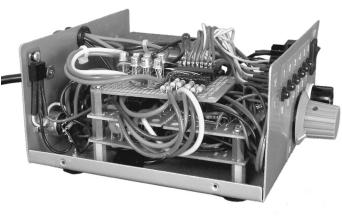

Figure 25—The schematic diagram for the external antenna relay box. All relays are DPDT, 250 V ac, 15 A contacts. R29 is used to limit the regulator current. Mount the regulator using TO-220 mounting hardware, with heatsink compound. With the exception of the normally closed and normally open contacts, all wiring is #22 solid copper wire.

D5-D11 — 1N4007. J3 — 8 pin external weatherproof

connector (or DB-9 with appropriate weather sealant).

K1-K7 — Omron LY2F-DC12 with 12 V coil. U7 — LM7812 +12 V regulator.

(B)

Figure 26 — At A, the external relay box. The LM7812 regulator is mounted to the bottom of the box. The relay normally open and normally closed contacts are wired in parallel using #12 solid copper. The two extra flange-mount SO-239 connectors at the upper right are for future expansion. At B, inside the control box. The bottom board in the enclosure, as well as the right half of the middle section, hold the ICOM circuit. The Yaesu interface is on the left side of the middle section. The top circuit board holds the DIP sockets and relay-selection transistors. All high voltage leads are insulated. The 7805 5-V regulator is mounted on the back panel using TO-220 mounting hardware, with heatsink compound.

over this wire to prevent it from shorting to the aluminum box.

The normally open and normally closed contacts are also wired in parallel. This can be done on the lugs themselves. For this, use #12 solid copper wire.

Mount the relays in the aluminum box, oriented so they can be wired together without difficulty. (See **Figure 26A**.) With the exception of the wire used for the relay coils (#22 solid wire), use #12 solid copper wire for the rest of the connections.

To eliminate the possibility of spikes or "back emf," a 1N4007 diode is soldered across the coil contacts of each relay. In addition, 0.01-µF capacitors across the diodes will reduce the possibility of stray RF causing problems with the relay operation.

Since the cable run from the shack to the tower can be quite long, consideration has to be given to the voltage drop that may occur. The relays require 12 V dc. The prototype used a 12 V dc regulator in the relay box, fed with 18 V dc (at 2 A) from the control box. If the cable run is not that long, however, you could just use a 12-V supply and skip the regulator.

One of the relays is used for lightning protection. When not in use, the relay grounds the line coming in from the shack. When the control box is activated, it applies power to this relay, thus removing the ground on the station feed line. All the antenna lines are grounded through the normally closed relay contacts. They remain grounded until the relay receives power from the control box.

CONTROL BOX

This is the heart of the system. The 18 V dc

power supply for the relays is located in this box, in addition to the Yaesu and ICOM decoder circuits and the relay-control circuitry. All connections to the relay box are made via an 8-position terminal barrier strip mounted on the back of the control box.

The front of the box has LEDs that indicate the selected antenna. A rotary switch can be used for manual antenna selection. The power switch and fuse are also located on the front panel.

The wiring schemes on the Yaesu and ICOM ACC sockets are so different that the unit shown in the photos has a 5-pin DIN connector for each rig on the control box. Since there is only one set of LEDs, use an 8-pin DIP header to select the appropriate control circuit for each radio. See Figure 26B. The unit is built with point-to-point wiring on project boards.

ICOM Circuitry

This circuit originally appeared in April 1993 QST and is modified slightly for this application. The original circuit allowed for switching between seven antennas (from 160 to 10 meters). The Band Data signal from the ICOM radios goes to a string of LM339 comparators. Resistors R9 through R15 divide the 8-V reference signal from the rig to provide midpoint references between the band signal levels. The LM339 comparators decide which band the radio is on. A single comparator selects the 1.8 or 10 MHz band because those bands are at opposite ends of the range. The other bands each use two comparators. One determines if the band signal is above the band level and the other determines if it is below the band level. If the signal is between those two levels, the appropriate LED and relay-selection transistor switch is turned on.

The ICOM circuit allows for manual antenna selection. The 8-V reference is normally taken directly from the ICOM ACC socket. If this circuit is to be used with other equipment, then a regulated 8-V source should be provided.

Yaesu Circuitry

The neat thing about Yaesu band data is that it's in a binary format. This means you can use a simple BCD decoder for band switching. The BCD output ranges from 1 to 9. In essence, you can switch among 9 antennas (or bands). Since the relay box switches just six antennas, steering diodes (D1 through D4 in Figure 24) allow the use of one antenna connection for multiple bands. One antenna connection is used for 17 and 15 meters, and another connection for 12 and 10 meters because the ICOM band data combines those bands. There is no control line or relay for a 30-meter antenna with this version of the project.

RFI has been reported to be caused by the CD4028 decoder IC (U5). Should this be the case for you, be sure the 7805 regulator is not oscillating and has the required bypass capacitors at the input and output. If the 7805 output is clean, add 0.01 μ F, 50 V ceramic bypass capacitors to all pins of the CD4028 (except pin 8, the ground pin).

DIP Sockets and Header

A project board holds the DIP sockets along with the relay keying transistors. This board is shown as the top layer in Figure 26B. The

Yaesu socket has $1-k\Omega$ resistors wired in series with each input pin. The other header connects directly to the ICOM circuitry.

The DIP header is used to switch the keying transistors between the ICOM and Yaesu circuitry. The LEDs are used to indicate antenna number. Use stranded wire (for its flexibility) when connecting to the LEDs.

Relay Keying Transistors

Both circuits use the same transistorkeying scheme, so you need only one set of transistors. Each transistor collector connects to the terminal barrier strip. The emitters are grounded, and the bases are wired in parallel to the two 16-pin DIP sockets. The band data turns on one of the transistors, effectively grounding that relay-control lead. Current flows through the selected relay coil, switching that relay to the normally open position and connecting the station feed line to the proper antenna.

Power Supply

The power supply is used strictly for the

relays. Other power requirements are taken from the rig used. There is room here for variations on the power supply theme; the parts used in this version were readily available.

6 A Raspberry-Pi Server/Client for Antenna Rotators

(This section is a summary of the Nov/Dec 2015 AMSAT Journal article "A Raspberry Pi Network Server/Client for Antenna Rotor," by Tom Doyle, W9KE. The complete article is available as a PDF document with the downloadable supplemental content. Changes by the authors of the netServer, LVP Tracker, or K5FR VSP Manager software may cause the functions described in this article to operate somewhat differently.)

With network connections becoming common in amateur equipment, this article describes a project that creates a network interface for an antenna rotator using the popular and inexpensive Raspberry Pi 2 single-board computer. It was originally designed to support satellite tracking with a Yaesu G-5500 rotator and LVB Tracker rotator control system but can be adapted to other uses and equipment. In addition, the

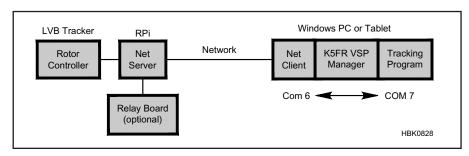

Figure 28 — The block diagram showing how to use the Net Server/Client to control an azimuth/elevation control rotator.

Raspberry Pi can control commonly available relay boards with up to four relays for antenna polarity, power switching, and other on/off functions. The net server system is shown in **Figure 27**. The system block dia-

gram is shown in Figure 28.

THE NET SERVER

A net server is a device used to create a network connection to a non-networked piece of equipment, in this case an antenna rotator controller. A net server can be especially useful when operating portable or from a remote location. The basic connections to the Raspberry Pi 2 (Raspi2) are shown in Figure 27: power, the RJ-45 Ethernet port, a USB connection to the LVB tracker board, and a five-wire connection to a relay control board. The USB and relay control board connections are optional, depending on station needs. The Model B version of the Raspberry Pi 2 running the default operating system, raspian wheezy was used for this project. Other models with equivalent resources may also be used.

Initial setup of the *Net Server* software (see the full article with the downloadable supplemental content) requires a keyboard, mouse and monitor be connected to the Raspi2. After the initial setup, it may be operated using a remote desktop connection. Since the Raspi2

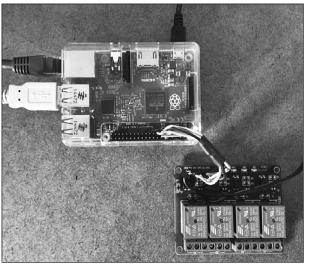

Figure 27 — A photo of the Rasberry Pi 2 system showing the four primary connections: power, Ethernet, USB, and relays.

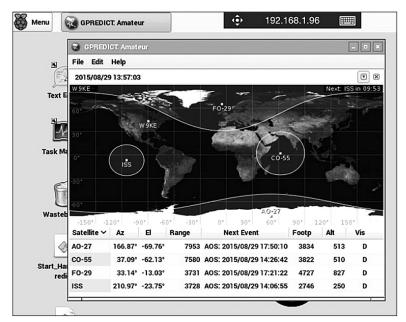

Figure 29 — A screen shot of an iPad running both a remote access program (*Microsoft Remote Desktop*) connected to the Net Server/Client system and a satellite tracking program (*GPredict*).

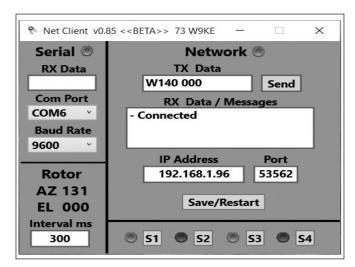

Figure 30 — The *Net Client* software connected to an LVP Tracker, showing the control interface for the LVP Tracker and serial communications configuration.

uses a multitasking operating system, it can run the *Net Server* program and another server program to allow access from a remote device at the same time. A Raspi operated without a local display, keyboard, or mouse is often referred to as "headless." (Complete setup and configuration instructions are included with the full article in the downloadable supplemental content.)

Figure 29 shows a screen shot of an iPad

running Microsoft Remote Desktop connected to Net Server. The Raspi2 is also running GPredict satellite tracking software. Access can also be obtained from a PC using Remote Desktop Connection. After the remote connection has been established, the Raspi2 can be operated from the remote device as if a keyboard, mouse, and monitor were connected directly to it. This helps reduce clutter in the shack and also reduces the cost of the

system. It is also a very important advantage when operating portable.

If an LVB Tracker is connected to the Raspi2, the current azimuth (AZ) and elevation (EL) for the rotator are shown in the lower left part of the window in the section labeled "Rotor." (See **Figure 30**.) This value is updated at an interval shown in the "Interval ms" box.

The group of four buttons and indicators in the bottom right of the window (S1 - S4)control four relays if a suitable relay board is attached. After clicking on the S1 button, a message will be sent to the Raspi2 running *Net Server*, instructing it to turn on relay 1. When this has been done, Net Server will send back a message indicating that relay 1 is activated and the indicator to the left of the S1 button will turn from red to green. The indicator button will not turn green immediately, only after a confirming "relay on" message is received. The indicator will not change at all if there is not a network connection to a working Net Server system. The system waits to see if the message was received. (The system cannot tell whether a relay board is installed, however.)

To move the rotator, enter a valid LVB Tracker/Yaesu GS-232 move command, then click the Send button and the rotator should move to the new position. The position information is shown in the Rotor portion of the display and will track the move with updates at an interval specified in the "Interval ms" text box.

If changes are made to the values in the window other than the "TX Data" text box, the Save/Restart button will turn yellow as a reminder to save the changes. By clicking on the Save/Restart button, the values will be saved and the program will automatically restart. When deciding what to hook up to the relays, take into account that the relays will all be turned off whenever the Net Server starts up.

The Serial section of the screen shows the controls used to configure the serial port that connect to external programs with a serial interface, such as the LVP Tracker software. K5FR VSP Manager software is used to set up a pair of virtual serial ports. One of the ports is connected to the external program such as an LVP Tracker and the other to Net Client using the check boxes in the Serial area of the Net Client window.

When the serial port connection is made, the indicator button to the right of the word Serial will turn green. In Figure 30, *Net Client* is connected to virtual port COM6 at 9600 baud and COM7 is connected to the tracking program. This allows the software to send messages to the rotator.

7 Audible Antenna Bridge

The audible antenna bridge (AAB) shown in **Figure 31** was designed by Rod Kreuter, WA3ENK. This project would help a visually impaired ham, but sighted hams will also find it very useful. (For example, tuning a mobile screwdriver antenna while you're driving.) The AAB is rugged and easy to use, both in the harsh light of day and in the dark of night. It's also inexpensive to build, and a kit is available.¹

An absorptive type of SWR meter, the AAB is used to indicate how close the match is between your transmitter and your antenna. Its output is a tone whose pitch is proportional to SWR. It also sends the SWR value in Morse code.

Unlike most SWR meters on the market, this one actually absorbs power from your transmitter while you're tuning, helping to protect your transmitter during tune-up. Many transmitters have SWR foldback capability and will decrease the output power if the antenna match is poor, but some do not.

By absorbing power in the AAB, no matter what you do at the antenna port, the transmitter never sees an SWR greater than 2:1. The trade-off is that 75% of your transmitter power ends up as heat in the bridge, so you need to switch out the AAB after you have tuned your antenna.

THEORY OF OPERATION

The AAB works on a principle taken right from the *ARRL Antenna Book*. The bridge consists of four impedances, or arms. See **Figure 32**. If three of the arms are $50\,\Omega$ resistors and the fourth is an antenna (or an antenna and tuner combination), then the bridge will be balanced when the antenna port is also $50\,\Omega$. Diodes D1 and D2 sample the forward and reverse voltages, respectively. A peripheral interface controller (PIC) with a 10 bit analog to digital converter (A/D) digitizes these voltages and calculates the SWR.

The SWR is used to control a hardware pulse width modulator that produces the output tone. It's also used by the Morse code routine to send the actual value of SWR, at 15 WPM with 5 WPM spacing.

The power that the AAB can handle during tune-up is a function of the resistors used in the three reference arms of the bridge. The 30 W noninductive resistors, R1-R3, are made by a number of companies but are not cheap. The bridge resistors must be noninductive. Don't use wire wound resistors!

Antenna tuning should be done with minimal power, and the AAB will work down to about 1 W. The 30 W resistors will handle tune-ups with about 60 W or perhaps 100 W for a short time. If you always remember to

Figure 31 — Front view of the audible antenna bridge.

turn down your transmitter power, and you tune up quickly, the bridge resistors could be perhaps 5 W for normal rigs and 1 W for ORP rigs.

BUILDING THE AAB

A PC board is a nice way to build the AAB, but you could easily construct such a simple circuit using ugly construction. Keep the wires short in the RF section. See **Figure 33**.

Use a heat sink for the noninductive resistors. Like many power devices, the power rating depends on getting the heat out! These resistors get really hot running at 10 or 20 W. See **Figure 34**. Use a big heat sink with heat sink compound, give yourself plenty of room in the cabinet and drill some holes to let the heat escape.

Switch S1 chooses TUNE/OPERATE and S2, the INQUIRE button, is used to report on various conditions, such as the SWR value in Morse code. You can eliminate the TUNE/OPERATE switch, but remember to remove the AAB from your feed line after tuning up.

To use the AAB in a QRP station, you may want to reduce resistors R4 and R5. They are sized so that a 25 W transmitter will not saturate the analog to digital converter (ADC) on the PIC when using fresh batter-

ies (more on this later). A good value for a 5 W transmitter would be about 20 k Ω . So long as the voltages at pin 12 and pin 13 of U1 are below the battery voltage, the system will work fine.

POWERING THE AAB

To save power the AAB uses a sleep mode. If you haven't pushed the INQUIRE button for about 5 minutes, the AAB will go to sleep after sending the letter N for "night night." During sleep the current draw is about 2 μ A. Pushing the switch while it's sleeping will wake up the AAB and it will send the letter U ("up").

The first four prototypes used four AAA batteries and a low-dropout 4.7 V regulator. This made for a nice stiff supply and very good battery life, with only one problem. Even though the PIC uses less than 2 μ A during sleep, the regulator uses 500 μ A. Battery data says that alkaline AA batteries will last 6 months at this level and AAA batteries about half that long. Consider adding an ON/OFF switch if you go this route.

The other option is to use batteries without a regulator. Normally you couldn't get away with this without providing a separate voltage reference for the ADC in the PIC. In this case it doesn't matter as much because SWR is a ratio of two voltages.

What does matter is the battery voltage with respect to the voltage produced by the RF signal. Diodes D1 and D2 rectify the RF and produce a dc voltage proportional to RF power. This voltage is divided by resistors R4, R6 and R5, R7. The voltage at the ADC inputs of the PIC, pins 12 and 13, must be less than the power supply voltage. With a regulated supply this isn't much of a problem, and if you're careful it can also work with unregulated batteries.

Microchip recommends that these parts be run on 2.5 to 5.5 V if you need the 10 bit ADC to be accurate. Many battery combinations will provide this, but consider lithium batteries instead of alkaline. The voltage from an alkaline battery begins to fall very early in its life and continues at a downward slope until it is exhausted. A lithium battery, on the other hand, provides a nearly constant voltage throughout its useful life. A 3.6 V AA size lithium should last a few years, but with the lower output voltage you may want to reduce R4 and R5. The final prototype used three AAA lithium batteries (each about 1.7 V when new), with no regulator or ON/OFF switch, which should last at least two years.

U1's ADC converter will saturate at some level. With new batteries, let's say this level is

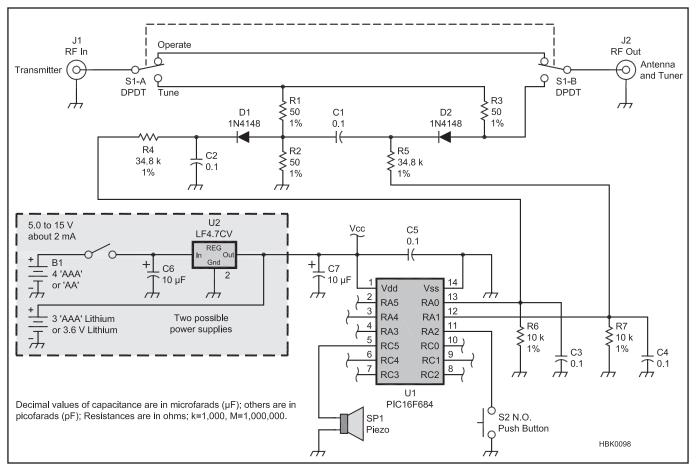

Figure 32 — Schematic and parts list of the AAB.

C1-C5 — 0.1 μ F ceramic. C6, C7 — 10 μF, 25 V electrolytic. D1, D2 — 1N4148.

Caddock noninductive (Mouser 684-MP930-50). R4, R5 — Resistor, 34.8 kΩ, 1%. R6, R7 — Resistor, 10 k Ω , 1%. S1 — DPDT (Digi-Key SW333-ND).

S2 — Momentary contact (Mouser 612-TL1105LF250Q).

SP1 — Piezoelectric buzzer EFB-RD24C411 (Digi-Key P9924-ND). U1 — PIC16F684 (Digi-Key PIC16F684-1/P-ND). Must be programmed before use. See Note 1.

U2 — LF4.7CV regulator (Mouser 511-LF47CV).

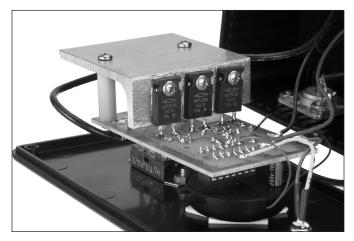

Figure 33 — Close-up view of three CaddockTO-220 style bridge resistors mounted on the heat sink.

Figure 34 — Interior view of the AAB, showing the battery pack at the bottom of the enclosure.

25 W when the power supply is 4.5 V. When the power supply has fallen to 3.5 V, the RF level that will saturate the converter will be 15 W. So if you find that the output of your rig, which used to be fine, is now saturating the ADC, it's time to change batteries.

USING THE AAB

Connect your transmitter to the INPUT and your antenna/tuner to the OUTPUT. Turn your transmit power down to 5 or 10 W and put S1 in the TUNE position. Wake the AAB up by pushing the INQUIRE button. Key your transmitter in a mode with some carrier power. The AAB should start to produce a steady tone. Adjust your tuner or antenna for the lowest tone pitch. Press the INQUIRE button for the numeric SWR value.

When the AAB is operating normally, it produces a tone proportional to SWR. The tone ranges from 250 Hz at an SWR of 1.0:1, rising to 4450 Hz at an SWR of about 15:1. Errors can occur and at times the AAB can't make a measurement. If an error occurs, either a high pitched tone or no tone is pro-

duced. Pushing the INQUIRE button will give you more information. Five different conditions can occur:

Normal operation. A tone proportional to SWR is produced. Press INQUIRE and a two digit SWR value is sent, separated by the letter R (Morse for the decimal point character).

Error 1. The forward power is too low for a reliable measurement. No tone is produced. INQUIRE button sends letter L (low).

Error 2. Forward power is too high (almost saturating the ADC). A pulsing tone proportional to SWR is produced. However, if the ADC is saturated this value might be meaningless. INQUIRE button sends letter \$ (saturated).

Error 3. SWR is greater than 9.9:1. A tone proportional to SWR is produced. INQUIRE button sends letter H (high).

Error 4. The reverse voltage is greater than the forward voltage. Two things can cause this error. You might be near a high power transmitter, or you connected the transmitter to the output port. No tone is produced. INQUIRE button sends letter F (fault).

The PIC used in this design could be used in a more standard SWR meter, such as those with a transformer type sensor. As long as the meter produces a forward and reverse voltage that you can scale to be from 0 to 3 up to 5 V (depending on your power supply choice), it will work just fine. However, the driving impedance of the voltage must be $10 \ k\Omega$ or less.

The author thanks the Ham Radio Committee of the National Federation of the Blind for inspiration, and Tom Fowle, WA6IVG, and Bill Gerrey, WA6NPC, of the Smith-Kettlewell Research Institute for testing prototypes.

¹A kit of parts including a printed circuit board is available from Q-Sat, 319 McBath St, State College, PA 16801. The price is currently \$30, postpaid. PC boards are available for \$7 postpaid and a programmed PIC is available for \$6 postpaid. Source code for an unprogrammed PIC is available on the ARRL Web site. Go to www.arrl.org/qstin-depth and look for Kreuter0607.zip in the 2007 section.

8 A Trio of Transceiver/Computer Interfaces

Virtually all modern Amateur Radio transceivers (and many general-coverage receivers) have provisions for external computer control. Most hams take advantage of this feature using software specifically developed for control, or primarily intended for some other purpose (such as contest logging), with rig control as a secondary function.

Unfortunately, the serial port on most radios cannot be directly connected to the serial port on most computers. The problem is that most radios use TTL signal levels while most computers use RS-232-D.

The interfaces described here simply convert the TTL levels used by the radio to the RS-232-D levels used by the computer, and vice versa. Interfaces of this type are often referred to as level shifters. Two basic designs,

one having a couple of variations, cover the popular brands of radios. This article, by Wally Blackburn, AA8DX, first appeared in February 1993 *QST*.

TYPE ONE: ICOM CI-V

The simplest interface is the one used for the ICOM CI-V system. This interface works with newer ICOM and Ten-Tec rigs. **Figure 35** shows the two-wire bus system used in these radios.

This arrangement uses a CSMA/CD (carrier-sense multiple access/collision detect) bus. This refers to a bus that a number of stations share to transmit and receive data. In effect, the bus is a single wire and common ground that interconnect a number of radios and computers.

The single wire is used for transmitting and receiving data. Each device has its own unique digital address. Information is transferred on the bus in the form of packets that include the data and the address of the intended receiving device.

The schematic for the ICOM/Ten-Tec interface is shown in **Figure 36**. It is also the Yaesu interface. The only difference is that the transmit data (TxD) and receive data (RxD) are jumpered together for the ICOM/Ten-Tec version.

The signal lines are active-high TTL. This means that a logical one is represented by a binary one (+5 V). To shift this to RS-232-D it must converted to -12 V while a binary zero (0 V) must be converted to +12 V. In the other direction, the opposites are needed: -12 V to

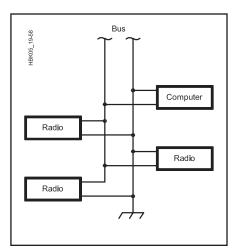

Figure 35 — The basic two-wire bus system that ICOM and newer Ten-Tec radios share among several radios and computers. In its simplest form, the bus would include only one radio and one computer.

+5 V and +12 V to 0 V.

U1 is used as a buffer to meet the interface specifications of the radio's circuitry and provide some isolation. U2 is a 5-V-powered RS-232-D transceiver chip that translates between TTL and RS-232-D levels. This chip uses charge pumps to obtain ± 10 V from a single ± 5 -V supply. This device is used in all three interfaces.

A DB25 female (DB25F) is typically used at the computer end. Refer to the discussion of RS-232-D earlier in the chapter for 9-pin connector information. The interface connects to the radio via a 1/8-inch phone plug. The sleeve is ground and the tip is the bus connection.

It is worth noting that the ICOM and Ten-Tec radios use identical basic command sets (although the Ten-Tec includes additional commands). Thus, driver software is compatible. The manufacturers are to be commended for working toward standardizing these interfaces somewhat. This allows Ten-Tec radios to be used with all popular software that supports the ICOM CI-V interface. When configuring the software, simply indicate that an ICOM radio (such as the IC-735) is connected.

TYPE TWO: YAESU INTERFACE

The interface used for Yaesu rigs is identical to the one described for the ICOM/Ten-Tec, except that RxD and TxD are not jumpered together. Refer to Figure 36. This arrangement uses only the RxD and TxD lines; no flow control is used.

The FT-990 and FT-1000/FT-1000D use an emitter follower as the TTL output. If the input impedance of the interface is not low enough to pull the input below threshold with nothing connected, the FT-990/FT-1000 (and perhaps other radios) will not work reliably. This can be corrected by installing a 1.5 k Ω resistor from the serial out line to ground

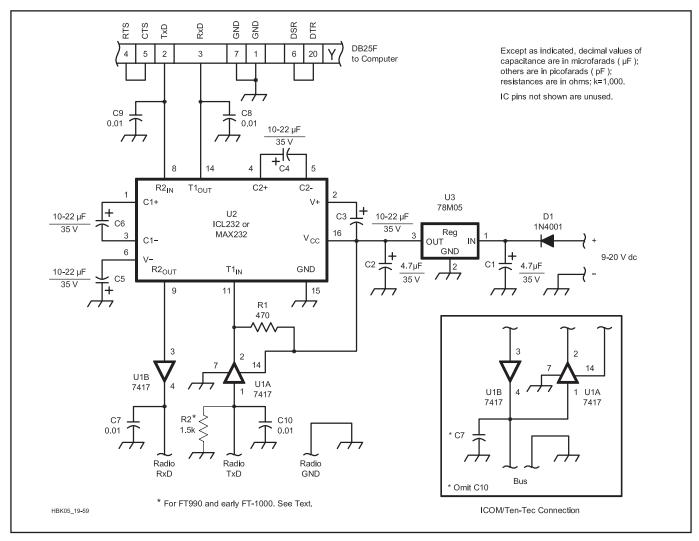

Figure 36 — ICOM/Ten-Tec/Yaesu interface schematic. The insert shows the ICOM/Ten-Tec bus connection, which simply involves tying two pins together and eliminating a bypass capacitor.

C7-C10 — 0.01-µF ceramic disc.

U1 — 7417 hex buffer/driver.

U2 — Harris ICL232 or Maxim MAX232.

(R2 on pin 1 of U1A in Figure 36.) Later FT-1000D units have a 1.5 k Ω pulldown resistor incorporated in the radio from the TxD line to ground and may work reliably without R2.

The same computer connector is used, but the radio connector varies with model. Refer to the manual for your particular rig to determine the connector type and pin arrangement.

TYPE THREE: KENWOOD

The interface setup used with Kenwood radios is different in two ways from the previous two: Request-to-Send (RTS) and Clear-to-Send (CTS) handshaking is implemented and the polarity is reversed on the data lines. The signals used on the Kenwood system are active-low. This means that 0 V represents a logic one and +5 V represents a logic zero. This characteristic makes it easy to fully isolate the radio and the computer since a

signal line only has to be grounded to assert it. Optoisolators can be used to simply switch the line to ground.

The schematic in **Figure 37** shows the Kenwood interface circuit. Note the different grounds for the computer and the radio. This, in conjunction with a separate power supply for the interface, provides excellent isolation.

The radio connector is a 6-pin DIN plug. The manual for the rig details this connector and the pin assignments.

Some of the earlier Kenwood radios require additional parts before their serial connection can be used. The TS-440S and R-5000 require installation of a chipset and some others, such as the TS-940S require an internal circuit board.

CONSTRUCTION AND TESTING

The interfaces can be built using a PC

board, breadboarding, or point-to-point wiring. PC boards and MAX232 ICs are available from FAR Circuits. The PC board template is available with the downloadable supplemental content.

It is a good idea to enclose the interface in a metal case and ground it well. Use of a separate power supply is also a good idea. You may be tempted to take 13.8 V from your radio — and it works well in many cases: but you sacrifice some isolation and may have noise problems. Since these interfaces draw only 10 to 20 mA, a wall transformer is an easy option.

The interface can be tested using the data in **Tables 6, 7** and **8**. Remember, all you are doing is shifting voltage levels. You will need a 5-V supply, a 9-V battery and a voltmeter. Simply supply the voltages as described in the corresponding table for your interface and check for the correct

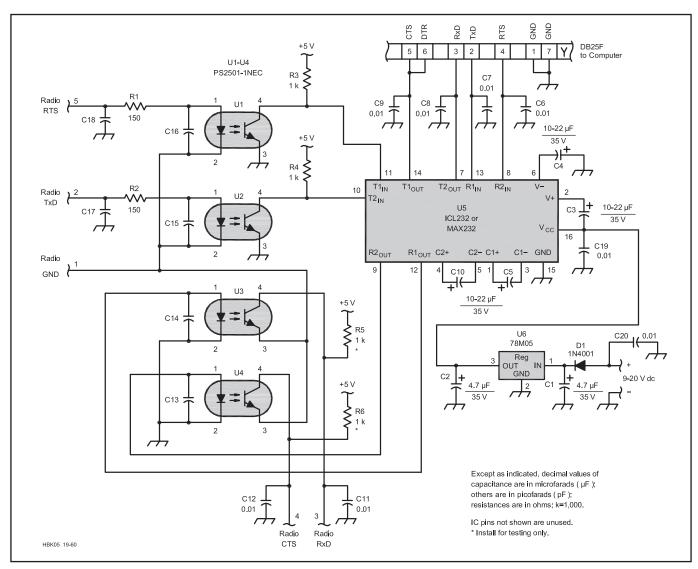

Figure 37 — Kenwood interface schematic. C6-C9, C11, C12, C17, C18 — 0.01-µF ceramic disc.

+5 V to Radio-2	+8 to +12 V at PC-3
+9 V to PC-2	+5 V to Radio-3
–9 V to PC-2	0 V at Radio-3

voltage on the other side. When an input of -9 V is called for, simply connect the positive terminal of the battery to ground.

During normal operation, the input signals to the radio float to 5 V because of pullup resistors inside the radio. These include RxD on the Yaesu interface, the bus on the ICOM/Ten-Tec version, and RxD and CTS on the

Table 7 ICOM/Ten-Tec Interface Testing

Apply	Result
GND to Bus	+8 to +12 V at PC-3

+9 V to PC-2	0 V at Radio RxD
-9 V to PC-2	+5 V at Radio RxD

Kenwood interface. To simulate this during testing, these lines must be tied to a 5-V supply through 1-k Ω resistors. Connecting these to the supply without current-limiting resistors will damage the interface circuitry. R5 and R6 in the Kenwood schematic illustrate this. They are not shown (but are still needed) in the ICOM/Ten-Tec/Yaesu schematic. Also, be sure to note the separate grounds on

the Kenwood interface during testing.

Another subject worth discussing is the radio's communication configuration. The serial ports of both the radio and the computer must be set to the same baud rate, parity, and number of start and stop bits. Check your radio's documentation and configure your software and the radio to have identical communications settings.

9 A Simple Serial Interface

A number of possibilities exist for building an RS-232-to-TTL interface level converter to connect a transceiver to a computer serial port. The interface described here by Dale Botkin, NØXAS, is extremely simple, requiring only a few common parts.

Most published serial interface circuits fall into one of the following categories:

- •Single chip, MAX232 type. These are relatively expensive, require several capacitors, take up lots of board space and usually require ordering parts.
- •Single chip, MAX233 type. This version doesn't need capacitors. Otherwise it shares most of the characteristics of the MAX232 type device, but is even more expensive.
- •Transistors. Usually transistor designs use a mix of NPN and PNP devices, four to eight or more resistors, and usually capacitors and diodes. This is just too many parts!
- •Other methods. Some designs use series resistors, or TTL logic inverters with resistors. The idea is that the voltages may be out of specification for the chip, but if the current is low enough it won't damage the device. This is not always safe for the TTL/CMOS device. With just a series resistor the serial data doesn't get inverted, so it requires the use of a software USART. It can work, but it's far from ideal.

A SIMPLER APPROACH

The EIA-232 specification specifies a

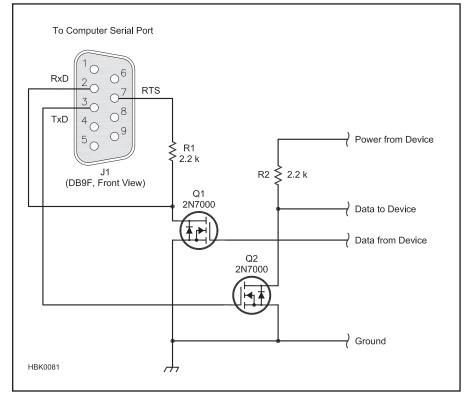

Figure 38 — Schematic for the simple serial interface.

J1 — DB9F or connector to fit device serial port. Note that pin assignments for RxD, TxD and RTS are different on DB25 connectors. Q1, Q2 — Small signal MOSFET, 2N7000 or equiv.

signal level between ±3 V and ±12 V for data. The author looked at data sheets for devices ranging from the decades-old 1489 line receiver to the latest single-chip solutions. Not a single device found actually required a negative input voltage! In fact, the equivalent schematic shown for the old parts clearly shows a diode that holds the input to the first inverter stage at or near ground when a negative voltage is applied. The data sheets show that a reasonable TTL-level input will drive these devices perfectly well.

Relieved of the burden of exactly replicating the PC-side serial port voltages, the interface shown in **Figure 38** is designed for minimum parts count and low cost — under \$1.

Why use MOSFETs for Q1 and Q2? In switching applications such as this, there are several advantages to using small signal MOSFETs over the usual bipolar choices like the 2N2222 or 2N3904. First, they need no base current limiting resistors — the MOSFET is a voltage operated device, and the gate is isolated from the source and drain. The gate on a 2N7000 is rated for ±20 V, so you don't need a clamping diode to prevent negative voltages from reaching the gate. They can also be had just as cheaply as their common bipolar cousins. (If sourcing 2N7000s is a challenge in Europe, the BS170 is basically identical except for the pins being reversed.) Now all that is needed is a drain limiting resistor, since the gate current is as close to zero as we are likely to care about.

Q1 gets its input from the TTL-level device. Q1 and R1 form a simple inverter circuit, with the inverted output going to pin 2 (RxD) of the serial connector. The pull-up voltage for RxD comes from pin 7 (RTS) of the serial connector, so the voltage will be correct for whatever device is connected — be it a PC or whatever else you have. Q2 and R2 are another inverter, driven by TxD from pin 3 of the serial connector. The pull-up voltage for R2 should be supplied by the low-voltage device — your radio or microcontroller project.

There you go. Two cheap little MOSFETs, two resistors. The 2.2 k Ω , $\frac{1}{4}$ W resistors seem to work with every serial port tried so far. The author has sold several hundred kits using this exact circuit for the serial interface without issues from any users. It's been tested with laptops, desktops, USB-to serial-converters, a serial LCD display, and even a Palm-III with an RS-232 serial cable. It's also been used with very slight modifications in computer interfaces for VX-7R and FT-817 transceivers. It's simple, cheap and works great — what more could you ask?

10 USB Interfaces For Your Ham Gear

Serial ports have disappeared from most new computers. The once-ubiquitous serial port, along with other interfaces that were once a basic part of every computer system, has largely been replaced by Universal Serial Bus (USB) ports. This presents problems to the amateur community because serial ports have been and continue to be the means by which we connect radios to computers for control, programming, backing up stored memory settings, contest logging and other applications. Radios equipped with USB ports are rare indeed, and many of the optional computer interface products sold by ham manufacturers are serial-only. The project described here by Dale Botkin, NØXAS, offers a solution.

THE UNIVERSAL SERIAL BUS

So what is USB, and how can it be used in the ham shack? The USB standard came about during the early 1990s as a replacement for the often inconvenient and frustrating array of serial, parallel, keyboard, mouse and various other interfaces commonly used in personal computer systems. The idea is to use a single interface that can handle multiple devices sending and receiving different types of data, at different rates, over a common bus. In practice, it works quite well because of the very well defined industry specification for signal levels, data formats, software drivers and so forth.

At least two and sometimes as many as six or more USB ports are now found as standard equipment on nearly all new computer systems. Support for USB ports and generic USB devices is built into most operating systems including *Windows*, *Linux*, *Solaris*, *Mac OS* and *BSD* to name a few. USB use has spread beyond computers, and the standard USB "B"

or the tiny 4-conductor "Mini B" connectors are now found on all manner of electronic devices including cameras, cell phones, PDAs, TVs, CD and DVD recorders, external data storage drives and even digital picture frames. USB is indeed becoming *universal*, as its name implies — everywhere, it seems, except for Amateur Radio gear!

The EIA-232 serial interface specification we have used for decades is just that — an electrical interface specification that defines voltage levels used for signaling. The asynchronous serial format most commonly used with serial ports defines how data is sent over whatever interface is being used. Any two devices using the same protocol and format can talk to each other, whether they are both computers, both peripheral devices (like printers, terminals or TNCs) or any combination. All that is required is the proper cable and the selection of matching parameters (speed, data bits, handshaking) on each end of the connection.

This is not the case with USB devices. USB uses a tiered-star architecture, with well defined roles for the host controller (your computer) and devices. Devices cannot communicate directly with each other, only with a host.

See Figure 39. At the top of the stack is the host controller device (HCD), usually your computer, which controls all communication within the USB network. The computer may have several host controllers, each with one or more ports. The host controller discovers, identifies and talks to up to 127 devices using a complex protocol. No device can communicate directly with another device; all communication is initiated and controlled by the host controller. As a result, you cannot simply connect two USB devices together and expect them to communicate. (Some USB printers will talk directly to digital cameras because the printer also has a host controller built in.)

As you have probably already figured out, moving from serial to USB is not a simple

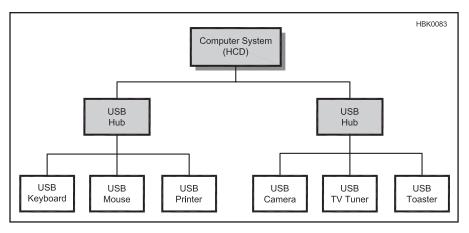

Figure 39 — Typical USB architecture.

matter of converting voltage levels or even data formats. USB devices all need some embedded "smarts," usually in the form of either a dedicated USB interface chip or a microcontroller using firmware to talk to the USB host. Where we could once use simple transistor circuits to adapt RS-232 serial to the TTL voltage levels used by many radios, we now must add the complete USB interface into the picture.

The USB specification is freely available and well documented, and there are books dealing with designing the software to use the interface. If you're starting from scratch it is a very daunting task to even understand exactly how USB works, let alone design and build your own USB-equipped device. If you're willing and dedicated enough, you can implement your own USB device using a fairly broad range of available microcontrollers. There are also dedicated function chips that implement a complete USB interface — or parts of it — in one or two devices.

Fortunately, several manufacturers have stepped up to make using USB relatively easy for the experimenter. One of the most commonly used solutions is from Future Technology Devices International (FTDI). FTDI manufactures a line of USB interface chips that plug into the Universal Serial Bus on one side and present a serial or parallel interface on the other side. The chips are quite versatile and are commonly used to add USB functionality to a wide range of devices ranging from cell phones to USB-to-serial cables. They are also available in several forms such as plug-in modules with a USB connector and the interface logic, all on a small PC board with pins that can be plugged into a standard IC socket.

CONSTRUCTION

This project uses an FT232R series chip from FTDI to bridge the USB interface from your computer to a TTL-level serial interface that can be adapted to use with many different ham rigs. The chip has built-in logic to handle the USB interface, respond to queries and commands from the computer, and send and receive serial data. By using special drivers available from FTDI (and built into *Windows* and many other systems), it can appear to your programs as a standard serial COM port.

Once the conversion to serial data is done, all that remains is to adapt the signals to the particular interface used by your equipment. In many cases, this serial data can simply be connected directly to the rig using the appropriate connector. In others it may require some extra circuitry to accommodate various interface schemes used by manufacturers. The most common is an open-collector bus type interface, which is easily accommodated using a few inexpensive parts.

Construction of this project can be handled in a couple of different ways. The FT232R series chips are available from various suppliers at low cost. Unfortunately they are only available in SSOP and QFLP surface mount packages that can be difficult to work with unless you use a custom printed circuit board. (An additional letter is tacked onto the part number to identify the package. For example, the FT232RL uses a 28-pin SSOP package.) There are SSOP-to-through-hole adapter boards available, but they are relatively expensive and still require some fine soldering.

Fortunately FTDI also sells a solution in the form of the TTL-232R (**Figure 40**). It incorporates a USB "A" connector, an FT232RQ chip and the required power conditioning on a tiny PCB encapsulated in plastic, all about the size of a normal USB connector. A 6-ft long cable terminates in a 6-position inline header that provides ground, +5 V, and TTL level TxD, RxD, RTS and CTS signals.

You can connect these signals directly to your own microprocessor projects and have an "instant" USB connection. You can also build a variety of interface cables or boards for use with different radios. This arrangement is ideal for the experimenter and the person who might need several different interfaces for use with several different rigs — like many of us! The cost of the TTL-232R cable is quite reasonable, in fact lower than the cost of having a prototype PCB made to build your own equivalent device. Of course that option is still available to those who need more flexibility.

USING USB IN THE SHACK

With the USB-to-serial conversion handled so easily, the only remaining task is to adapt the TTL-level serial interface of the FT232R to the interface used by your particular radio. In the case of some rigs, such as the Yaesu FT-817, Kenwood TM-G707A and many others, it's simply a matter of wiring up the right connector, as shown in **Figure 41**.

For communicating with individual ICOM and Ten-Tec rigs, one simple solution is to simply connect the transmit and receive data signals together and wire up a ½-inch stereo plug as shown in **Figure 42**. This will work with a single device connected, but lacks the open-collector drivers needed to be compatible with attaching multiple devices to the CI-V bus.

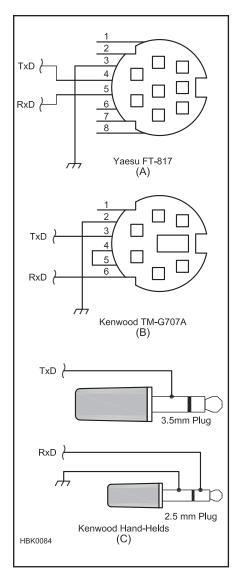

Figure 41 — Using the FTDI USB-to-serial interface with some radios is as simple as wiring up a connector. Connections for the Yaesu FT-817 are shown at A, the Kenwood TM-G707A (PG-4 type) at B, and Kenwood hand-helds (PG-5 type) at C. Ground, RxD and TxD connections are made to the 6-pin connector on the TTL-232R cable.

Figure 40 — The FTDI TTL-232R cable simplifies construction.

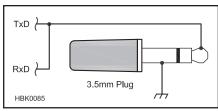

Figure 42 — The transmit and receive data signals can be connected together for use with a single Ten-Tec or ICOM CI-V device.

R1-R4 — 10 k Ω , ¼ W.

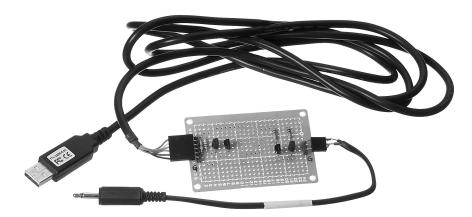

Figure 44 — The completed buffer board. Adapter cables for various radios plug into the header on the right edge of the board.

A LITTLE MORE VERSATILITY

Many hand-held transceivers use a single data line for both transmit and receive. This method is very similar to CI-V, but requires an open-collector or open-drain configuration for a single device. Some additional buffering is required to provide an interface to the rig.

Figure 43 shows the design of the general-purpose buffer board for use with various radios. This circuit simply provides a noninverting, open-drain buffer for data in each direction. Adapters for various rigs can be plugged into J2 with no further changes needed. Use of MOSFETs instead of their bipolar counterparts simply reduces the parts count. No additional resistors are needed to limit base current, as you would need when using 2N2222 or similar transistors. Parts can be mounted on a small project board as shown in Figure 44.

This arrangement turns out to be extremely versatile and will work with CI-V, FT-817,

Yaesu VX-series handhelds and the other rigs the author was able to test as well. All that is required is the proper adapter cable from the base interface board to the rig. Some examples are shown in **Figure 45**.

ADDING PTT

Handling PTT is quite simple, and it can be done either with or without isolation as shown in **Figure 46**. For a non-isolated PTT line, we can simply drive the gate of a 2N7000 or similar MOSFET from the FT232RL's RTS output. If you prefer an optically isolated PTT output, all you need to add is one resistor and an optocoupler such as a 4N27 or PS-7142. Note that the TTL-232R provides a 100 Ω resistor in series with the RTS signal (the same is true for TxD), so a smaller value resistor (R1) can be used for the optocoupler's input than you would normally use.

While connecting the data lines directly to the rig is a suitable solution for many ap-

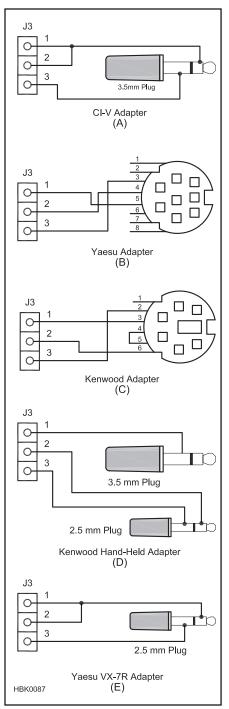

Figure 45 — Adapters for using the buffer board with various radios. J3 matches the adapter used on the buffer board.

plications, some Kenwood HF rigs require a different approach. They require inverted TTL-level data, and may experience "hash" noise from the computer when not using an isolated interface. **Figure 47** shows an optically isolated method of connecting to a Kenwood rig such as the TS-850S. Note that this has not been tested but the design is similar to numerous examples of serial interfaces for the TS-850S and similar radios.

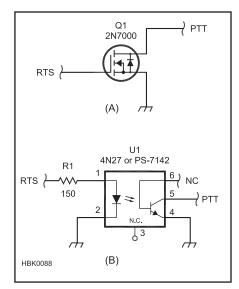

Figure 46 — PTT can be added either without isolation (A) or with an optoisolator (B).

It's probably only a matter of time before we start seeing the tiny USB "Mini B" connector appear on new ham gear. It has become inexpensive and easy to add USB to pretty much any product, and as serial ports become more and more rare the manufacturers will eventually face overwhelming consumer demand to switch. In the meantime, you can do a little homebrewing and use your new, serial port free computer to talk to all of your ham gear for very little cost.

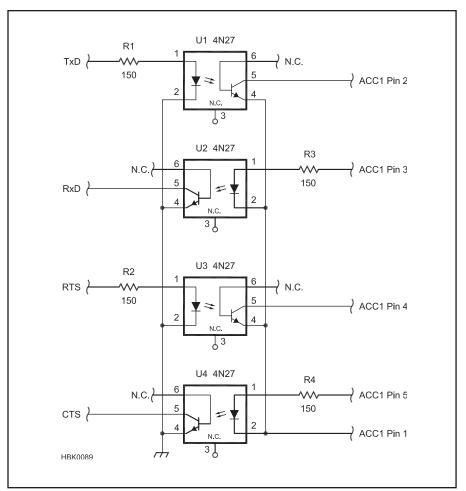

Figure 47 — Isolated Kenwood interface for the TS-850S and similar HF transceivers requiring inverted TTL-level data and isolated lines.

11 Keying and Tube Gear Interfaces

Switching and keying interfaces designed for today's solid-state, low-voltage equipment are not suited for direct connections to vacuum tube gear or other equipment that uses higher positive or negative voltages. This section presents a keying interface by NØXAS and two general-purpose interfaces that can be adapted to a variety of interface needs.

11.1 The Universal Keying Adapter

When Dale Botkin, NØXAS, was about to start restoring his old Heathkit HW-16, he decided it was time to explore what would be needed to key this tube rig using an electronic keyer. The key jack of this rig has a negative voltage, something like –85 V or more. Even the 2N7000 output of a solid-state keyer, rated at 60 V, would be no match for that. The Universal Keying Adapter (UKA) shown in **Figure 48** bridges the gap between a modern keyer and a classic tube-type transmitter, and

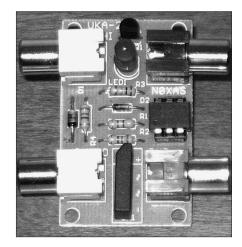

Figure 48 — The Universal Keying Adapter 2. Parts count is low, and it can easily be built on a small project board. A newer version is available as a kit from www. hamgadgets.com.

it can also be used to key older tube-type amplifier TR switching lines with solid-state transceivers that can't handle the voltage or current requirements.

KEYING SCHEMES

Older gear generally uses one of two keying schemes, grid-block or cathode keying. Grid-block keying requires that your key handle fairly high negative bias voltages, often in the 150 V range. Cathode keying is more demanding, with voltages up to +350 V or so. Most modern solid state keyers use a simple transistor output circuit suitable only for low-voltage, positive keying. Obviously, neither grid-block nor cathode keyed transmitters should be connected to such an output! At the very least it's going to damage the keyer.

Most grid-block keying adapters use one or two bipolar transistors and are designed specifically to key grid-block rigs. This is fine as far as it goes, but also requires that you have one setup for solid state rigs, another for grid-blocked rigs, and still another if you have a cathode keyed boat anchor as well. It's not an optimum solution. Of course one could use a relay to key just about anything, but relay contact noise would quickly get really irritating. Relays also eventually wear out, contacts get dirty and the coils can use quite a bit of current, meaning battery powered keyers will suffer from very limited battery life.

Solid-State Relays

Solid state relays exist, but they can be expensive. The author finally hit upon what seems to be an ideal solution. It's cheap, small, relatively low current, uses low voltage control and is capable of switching fairly high ac or dc voltages. Perfect! Crydom, NEC, Fairchild, Omron and other manufacturers make very similar small, inexpensive MOS-FET solid state relays. Suitable model numbers include the NEC PS7142 and PS7342, Fairchild HSR412, Omron G3VM-401B and others. Depending on the part selected they can handle up to a couple hundred milliamps and will switch up to 400 V ac or dc. All of this in a 6-pin DIP form factor, and for just a few bucks!

The MOSFET solid-state relay (SSR) is very similar to an optoisolator, but somewhat more versatile. Ac or dc loads can be switched, and the allowable load voltages are much higher than regular optoisolators. Driving the relay input involves supplying a few mA of current to turn on an LED inside the device. This requires about 1.4 V at a recommended forward current of 10 to 30 mA. The output is a pair of MOSFETs with common sources and a photo gate rather than a hard-wired gate. Turn on the LED and the MOSFETs conduct, turn off the LED and the MOSFETs shut off. Just like a relay, it's simple and elegant.

KEYING ADAPTER CIRCUITS

The addition of a simple transistor inverter allows the use of computer keying in parallel with input from a straight key, bug or keyer. This is handy, for example, to contesters using computers for keying who may need to send some information by hand from time to time. See Figure 49. The use of a 2N7000 MOSFET instead of the common NPN transistor makes it easier to accommodate both serial and parallel port use, since the gate will withstand up to 20 V positive or negative and does not need to be current limited. In this example, the value of R1 should be determined as mentioned earlier. R2's purpose is to keep the MOSFET gate from floating, so its value is not critical but 10 k Ω or 100 k Ω are good values.

The design eventually evolved to include a full-wave bridge rectifier allowing either ac or dc input, a Zener diode for voltage regulation and an LED keying indicator. The result was

the Universal Keying Adapter 2. The UKA-2 can accept any dc or ac power source up to about 30 V, and is adaptable to lower power battery operation by substituting or eliminating some of the power supply parts. A newer version is available in kit form from www.hamgadgets.com.

OTHER CONFIGURATIONS

It is worth noting that if only positive or only negative voltages will be used, the output current capacity can be greatly increased and the on-state resistance greatly decreased by connecting the two MOSFET drain outputs in parallel rather than serial. An example of this is shown in Figure 49B. For the HSR412, maximum load current increases from 140 mA for series output to 210 mA for parallel. An added feature of this arrangement is the presence of the intrinsic "body diodes" of the MOSFETS. If you are keying an amp that has an internal keying relay, this can serve to absorb some of the back EMF when the relay releases. Note that this arrangement requires that pin 5 of the IC be at a lower voltage than the other two pins — in other words, ground for positive keying, or –V for negative keying. Since the output is completely isolated from the input, the polarity of the output connector can be changed without the risk of exposing

your other gear to dangerous voltages.

Although the IC solid-state relays are good for a wide range of uses, there are applications that present more of a load than the device is able to safely handle even with the outputs in parallel. For loads of more than the rated device current, an external MOSFET switch can be used. Again, the resulting output is optically isolated from the input. Resistor R3 shown in Figure 49C keeps the gate of the 2N7000 MOSFET low until the input is activated, so its value is not critical. The gate voltage +V needs only to be within the safe range for the device selected; in most cases 12 V will do fine.

The UKA design works well with both grid-block and cathode keyed rigs, as well as solid state. It works quite well to key older tube power amplifiers with solid-state transceivers that are not equipped with suitable keying relays or circuits. The input works well with any rig, key, electronic keyer, serial or parallel port tried so far.

11.2 Interfacing High-Voltage Equipment to Solid-State Switching Circuits

More is required to connect HV (high-voltage) vacuum-tube gear to solid-state

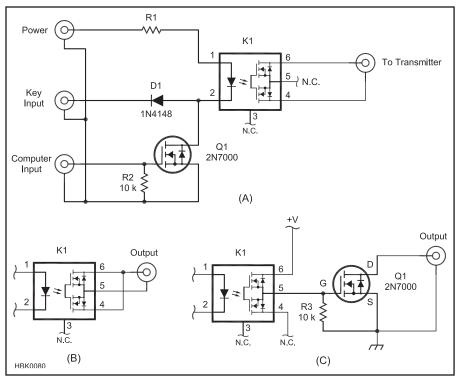

Figure 49 — The Universal Keying Adapter circuit with provisions for using computer keying in parallel with a hand key or keyer. Two methods of increasing the load current capacity are shown at B and C (see text for discussion).

K1 — Optically coupled solid-state relay, Fairchild HSR412 or equivalent. R1 — ¼ W resistor, varies with supply source voltage (see text). Use 150 or 220 Ω for two AA cells; 1 k Ω for 13.8 V dc power.

U1 — CD4049 CMOS inverting hex buffer, one section used (unused sections not shown; pins 5, 7, 9, 11 and 14 tied to ground).

accessories than a cable and the appropriate connectors. The solid-state switching devices used in some equipment will be destroyed if used to switch the HV load of vacuum tube gear. The polarity involved is important too. Even if the voltage is low enough, a key-line might bias a solid-state device in such a way as to cause it to fail. What is needed is another form of level converter.

MOSFET LEVEL CONVERTERS

While relays can often be rigged to interface the equipment, their noise, slow speed and external power requirement make them an unattractive solution in some cases. An alternative is to use power MOSFETs. Capable of handling substantial voltages and currents, power MOSFETs have become common design items. This has made them inexpensive and readily available.

Nearly all control signals use a common ground as one side of the control line. This leads to one of four basic level-conversion scenarios when equipment is interconnected:

- 1) A positive line must be actuated by a negative-only control switch.
- 2) A negative line must be actuated by a positive-only control switch.
- 3) A positive line must be actuated by a positive-only control switch.
- 4) A negative line must be actuated by a negative-only control switch.

In cases 3 and 4 the polarity is not the problem. These situations become important when the control-switching device is incapable of handling the required open-circuit voltage or closed-circuit current.

Case 1 can be handled by the circuit in **Figure 50A**. This circuit is ideal for interfacing keyers designed for grid-block keying to positive CW key lines. A circuit suitable for case 2 is shown in Figure 50B. This circuit is simply the mirror image of that in Figure 50A with respect to circuit polarity. Here, a P-channel device is used to actuate the negative line from a positive-only control switch. The values of R1, R2, and the Zener voltage for D1 must be determined based on the keying device.

Cases 3 and 4 require the addition of an inverter, as shown in **Figure 51**. The inverter provides the logic reversal needed to drive the gate of the MOSFET high, activating the control line, when the control switch shorts the input to ground.

Almost any power MOSFET can be used in the level converters, provided the voltage and current ratings are sufficient to handle the signal levels to be switched. A wide variety of suitable devices is available from most large mail-order supply houses.

12 PICAXE-Based Timer

This project by Darrell Davis, KT4WX (www.kt4wx.org) was originally published in the April 2016 issue of *QST*. The full article, including programming details, a flow chart for the software, and associated files are included in this book's downloadable supplemental information.

This PICAXE microcontroller-based timer is a programmable replacement for analog IC-based timers. It is a simple design that is an excellent "first microcontroller" project if you are unfamiliar with microcontrollers and software development. The program has two timer modes — 3 minutes (for repeater use to prevent timeouts) and 10 minutes (for extended QSOs to satisfy FCC requirements for station identification).

The time schematic diagram in **Figure 52** is based on the low-end eight-pin PICAXE 08M2 microcontroller. Pin 1 is + V_{cc} and pin 8 is ground. The circuit uses three discrete LEDs controlled by pins 3, 5, and 6 to indicate timer status. Pin 7 is used for serial outgoing data to a programmer and pin 2 is the incoming data from the programmer. R1 and R2 control the voltage at pin 2 to prevent the input from "floating" when the programmer is not connected which could cause unstable operation. Pin 4 acts as a reset input along with pull-up resistor R3 and switch S2.

Construction is not critical and the circuit can be assembled using point-to-point wiring on perfboard as shown in **Figure 53**. The assembled circuit can be installed in a standalone enclosure or used as a module in a larger project. If the LEDs are separated from the controller assembly by more than an inch or two, add 0.01 μF ceramic capacitors across the diodes to prevent RFI to the circuit or from the LEDs rectifying a strong local RF signal and generating harmonics.

Any voltage source from 3 to 5 V dc with a 50 mA capacity is adequate to power the circuit. A 7805-based regulator is included in the schematic. A lithium-ion battery such as a CR2032-style coin cell can be used to power the circuit for portable or mobile use as shown in Figure 52.

13 An Arduino-Based Knob Box for SDR

The following section is based on the article of the same name by Michael Stott, VE3EBR, first printed in the Radio Amateurs of Canada magazine *The Canadian Amateur (TCA)*. The complete article and supporting files are provided with the downloadable supplemental content and online at the websites referenced in the article.

SDR equipment is becoming more and more popular with amateurs, displacing analog electronics and changing the way amateurs operate and even think of the radio spectrum. The user interface of most SDR radios is implemented as a PC screen with mouse and keyboard controls that are easy and inexpensive to implement but not always the most responsive or intuitive way of controlling or performing a function — a physical knob or switch often works better for frequently used functions.

VE3EBR created the "SDR Knob Box" to replace some of the Flex-5000's *PowerSDR* screen controls with knobs and switches.

An Arduino interfaces with the knobs and switches, then sends the appropriate commands to the computer software (DDUtil) which then controls the SDR. In addition, switches and indicators are also included for controlling a standalone Yaesu rotator in association with the DXLab software.

Based on the Arduino microprocessor with all of its supporting software tools and hardware accessories, this project lends itself well to being adapted to any set of functions desired for an SDR transceiver or any computercontrolled device.

The author discovered an article by Anthony Good, K3NG, that describes an Arduino-based interface/controller for the rotator and decided to use this design as the basis for adaptation. The whole unit is powered from the Arduino USB connection.

HARDWARE DESIGN

The knob box is based on three small potentiometers, a pair of 1/4-inch-bushing toggle

switches, and a rotary shaft encoder with 24 detents and a nice silky "feel" to it (Panasonic EVQ-VBMF0124B/ Digikey P80685-ND). **Figure 54** shows the schematic of the knob box hardware.

The three potentiometers are allocated to Audio Gain, RF Gain (AGC-T on the author's Flex 5000), and RF Drive, arranged vertically to correspond to the control positions on the *PowerSDR* "panel." One of the toggle switches had a center-OFF position so it was allocated to TX/RX/Tuneup and a two-position switch to Monitor ON/OFF. The mechanical shaft encoder was dedicated to tuning the RF frequency. Red and green LEDs to show which direction the rotator was turning were mounted on the box panel using rubber grommets.

The selection of type and number of controls is pretty arbitrary and one could accommodate almost any combination within the limits of the Arduino's six analog inputs, eight digital I/O ports, and six digital I/O/

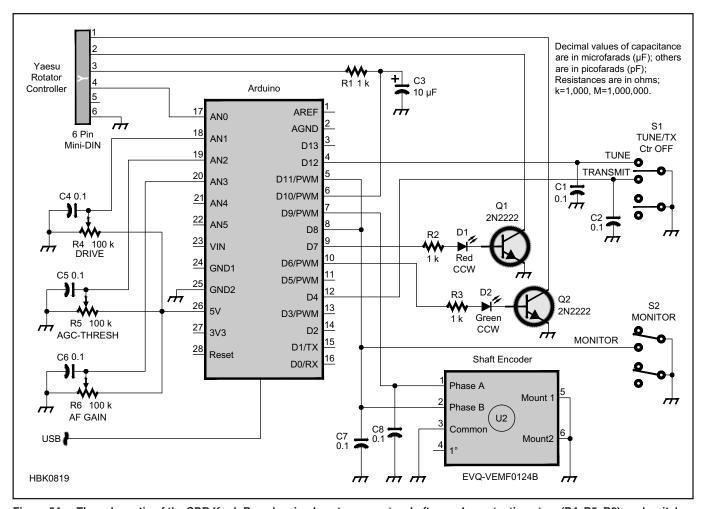

Figure 54 — The schematic of the SDR Knob Box showing how to connect a shaft encoder, potentiometers (R4, R5, R6), and switches (S1 and S2) to the Arduino microcontroller.

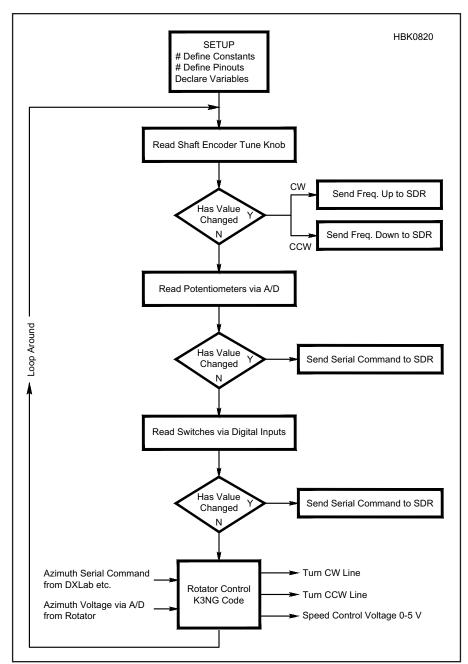

Figure 55 — Flow chart showing the control loop for the Arduino microcontroller. Once the setup process is complete, the software enters and remains in a loop to sense changes of the control positions or settings and generate commands to the SDR transceiver accordingly.

PWM_analog_outputs. Shaft encoders could be used rather than potentiometers but the "absolute" nature of the potentiometer position lends itself well to controls for setting levels rather than the relative or incremental output of an encoder, which is better suited to controlling changes such as tuning.

SOFTWARE DESIGN NOTES

Software for the unit was created by grafting on the code for responding to the potentiometers, switches, and so forth onto

Figure 56 — The SDR Knob Box replaces software controls such as click boxes and sliders with physical knobs and switches read by an Arduino microcontroller and then relays the appropriate commands to an SDR transceiver.

the K3NG rotator controller code. When the unit is switched on, the program stored in the onboard flash memory of the Arduino loads automatically and executes. It runs all the setup functions once and then begins a continuous looping process as shown by the flow chart in **Figure 55**. (All C language code is available at **wp.rac.ca/tca-content**.)

The functionality is quite simple. The Arduino reads the status of the various knobs and switches and compares the most recent state to the previous state. If something has changed it outputs a command to the SDR; otherwise it does nothing and continues looping.

The SDR software communicates with external programs by means of virtual COM ports and Virtual Audio Cables. The SDR interface utility software is *DDUtil* (version V3.x was used in the development of this project) is required. This free software provides a host of interfacing facilities between accessory equipment, rotators, digital mode software, and the Flex-5000 CAT computer control port. **Figure 56** shows the completed Knob Box.

14 An Audio Intelligibility Enhancer

Here's a simple audio processor (**Figure 57**) described by Hal Kennedy, N4GG, that can improve intelligibility, particularly for those with degraded high-frequency hearing. It might just give you an edge in that next DX pileup.

What we understand (intelligibility) of what we hear or detect is strongly affected by the end-to-end frequency response of a given communications circuit. Our equipment typically has a fixed audio bandwidth spanning about 300 Hz to 2700 Hz for SSB operation, but our hearing varies widely from operator to operator and it sometimes varies widely for an individual over the course of his or her life.

Speech intelligibility has been studied extensively since the 1940s. In brief, the "human speech signal" can be thought of as being made up of vowel and consonant sounds. The vowel sounds are low in frequency, with fundamental frequencies typically between 100 Hz and 400 Hz, and harmonics as high as 2 kHz. Consonant sounds occupy higher frequencies — typically from 2 kHz to as high as 9 kHz. (See "Speech Intelligibility Papers" at www.meyersound.com/support/papers/ speech/). In spoken English, vowel sounds contain most of the energy in the speech signal, while consonant sounds are short, noiselike, and convey the majority of intelligibility. When consonants are not heard well, it sounds like the speaker is mumbling. It becomes difficult to distinguish F from S and D from T.

Frequently, hearing degradation manifests itself both as a loss of sensitivity over all frequencies and a frequency dependent loss where the sensitivity of our hearing degrades as the frequency increases. Sensitivity loss that is flat over frequency does not affect intelligibility, assuming that levels are high enough to be heard. A simple loss of sensitivity can be addressed by turning up the AF gain! Unfortunately, turning up the gain does not compensate for frequency-dependent loss, and frequency-dependent loss does degrade intelligibility by reducing the ability to hear the consonants in human speech. A quick Web search for "human hearing" will yield a multitude of sites describing the basic concepts.

The author's audiology test results are shown in **Figure 58**. Audiologists refer to this pattern as *age induced hearing loss* — a roll-off of hearing sensitivity as frequency increases. Fortunately, intelligibility can be improved significantly for those with this common condition, by simply adding amplification that increases as a function of frequency.

Hearing deficiencies can be much more complex than the typical high frequency loss associated with aging. One's hearing can include notches and/or peaking as a function of frequency, as well as significant mismatch

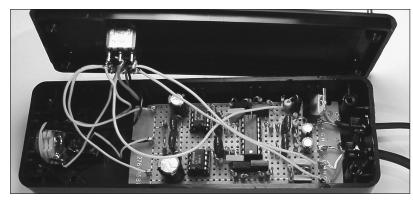

Figure 57 — The audio intelligibility enhancer is a compact audio processor that can help to compensate for degraded high-frequency hearing.

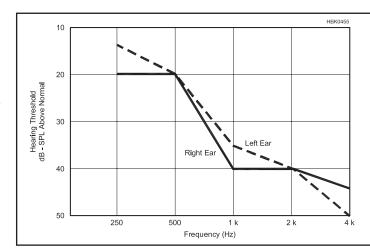

Figure 58 — The author's audiology exam results. Threshold sensitivity loss as a function of frequency is commonly associated with aging.

between the left and right ears. Most of these can be addressed through use of audio circuits whose gain approximates the inverse function of the hearing problem(s). Analog circuit designs become complex when more than a simple high-pass or single-notch filter is required. Modern high-end hearing aids use DSP circuits that break the audio spectrum into narrow frequency bands, each with programmable gain.

A professional audiology exam and threshold sensitivity test results are recommended as the starting point for determining how much, if any, audio shaping might improve your ham radio activities.

A VARIETY OF PRACTICAL OPTIONS

The author's operating interests require stereo operation to make significant use of a transceiver's dual receiver function when chasing DX, and to operate two radios simultaneously in contests. In each case operation is in stereo, with each ear dedicated to one of the two receivers. Monaural designs also have

a potential drawback, in that the frequency response adjustments apply equally to both ears. In some cases the frequency response of each ear is different.

Stereo equalizers have been around for decades. The most basic are four-band graphic equalizers; they have adjustments to provide up to about 12 dB of gain or attenuation across frequency bands that are centered at four frequencies, each frequency typically one octave above the next (an octave is a doubling of frequency). Seven, 10, 12 and 15 band equalizers are readily available, allowing for finer tailoring of amplification characteristics as the number of bands go up and the frequency range for each band gets smaller.

Parametric equalizers are also available — these differ from graphic equalizers in that the center frequency and bandwidth of each filter element is adjustable. Prices are very reasonable.

An equalizer is a near-perfect solution to compensating for hearing deficiencies, and the ability to readily adjust gain at multiple frequencies allows optimizing via experimentation. Many equalizers are strictly low-level devices and lack sufficient output power to directly drive headphones, requiring an amplifier if the equalizer is to be inserted between rig and headphones.

Some transceivers include adjustable audio DSP circuits for receive as well as transmit audio. It may be possible to adjust the audio response of your transceiver to improve intelligibility without the use of an external device.

CIRCUIT DESCRIPTION

The heart of this audio intelligibility enhancer (AIE) is what audiophiles refer to as a high-pass shelving filter. Shelving filters are sometimes used in high-end audio systems to compensate for deficiencies in crossover networks or loudspeakers. The basic circuit and its frequency response are shown in Fig**ure 59**. Note that the shape of this response curve is the inverse of the hearing response of Figure 58. Referring to Figure 59, the circuit provides a gain, A_{V1}, equal to 1.0 for frequencies somewhat below f_1 and a higher gain, A_{V2} , that is given by $A_{V2} = 1 + R2/R1$ for frequencies somewhat above f_2 . Frequency f_1 is given by $f_1 = 1/[2\pi C(R1+R2)]$, and frequency $f_2 = 1/[2\pi C(R1+R2)]$ $1/(2\pi CR1)$. Conveniently available component values of R1 = 1.33 k Ω , R2 = 6.65 k Ω , and $C = 0.047 \mu F$ yield a high frequency gain, $A_{V2} = 6.0$, and cut-on and cut-off frequencies of $f_1 = 425$ Hz, and $f_2 = 2550$ Hz. With these values, the circuit gain rises at an average of 3 dB per octave from 300 Hz to 2700 Hz—the frequency range for SSB transmission. For those interested in modifying the design, or using a shelving filter for other purposes, it's important to note that rearranging the equations yields: $f_2/f_1 = A_{V2}$. The ratio of the two break frequencies always equals the maximum gain.

Figure 59 also shows a feedback capacitor, C_f , which, while not contributing to the shelving filter function, is included as good design practice. The LM324 op amps used to implement the filters have gain-bandwidth products in excess of 1 MHz. Operating them with gain at frequencies above the useful limits of our hearing (and all the way out to beyond 1 MHz) is an open invitation for RFI prob-lems and unwanted high frequency noise. So, feedback capacitor C_f provides high frequency gain roll-off above the frequency $f = 1/(2\pi C_f R2)$ which for the value of C_f in this design $(0.0015 \ \mu F)$ is $16.8 \ kHz$.

Figure 60 is the complete schematic for the AIE. Two shelving filters, as described above, are used in series in each audio channel. Two filters in series provide sufficient gain change versus frequency to approximately match the author's high frequency hearing loss, which has a slope of about -7.5 dB/octave across the audiologist's measuring points from 250 Hz to 4 kHz. Two filters in series provide +6 dB/octave gain change from 300 Hz to 2700 Hz and 31 dB of total gain ($A_{Vtotal} = A_{V2} \times A_{V2} = 6 \times 6 = 36$ or about 31 dB). Some

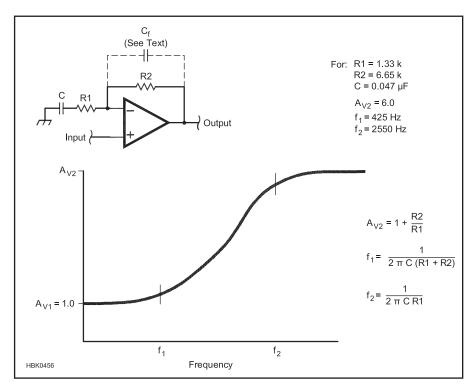

Figure 59 — Schematic and frequency response for a high-pass audio shelving filter.

tips for tailoring the circuit to your hearing are included in the next section.

The shelving filters are followed by LM386 audio amplifiers (U2, U3). These provide sufficient output power to drive headphones or small speakers. LM386s have a built-in voltage gain of 20, so they are preceded by 20:1 voltage dividers (R7+R8, R17+R18) to maintain an end-to-end gain of 1 at low frequencies.

Voltage regulator U4 provides regulated and filtered dc voltage to the shelving filters and the output stages. Current draw for the AIE is approximately 35 mA from a +13.6 V dc source, if the LED pilot light (D1) is included. D1 draws 10 mA by itself, however, and R21 and D1 can be deleted if current consumption is a concern. Supply voltage is not critical — anything from 12 to 18 V dc will work.

Capacitors C1 and C10 are used to prevent RFI, by bypassing to ground RF that may enter at the inputs. The original AIE without these capacitors suffered interference from loud distorted sounds (unrectified SSB RF) during transmit. C1 and C10 eliminated RFI problems, but they could be insufficient in the presence of large RF fields. If necessary, additional RF filtering can be achieved by adding RF chokes in series with both audio input and output lines.

TAILORING THE DESIGN TO YOUR HEARING

The AIE design presented here is intended to address high frequency hearing loss, and not other hearing deficencies. This AIE design does, however, have a reasonable amount of flexibility for tailoring to an individual's hearing.

The design as it is presented in Figure 60 includes two shelving filters per channel and switch S1. S1 allows selection of one (3 dB/ octave amplification) or two (6 dB/octave amplification) filter stages. If you are the only operator of your station and you know your hearing deficiency is less than about 5 dB/octave, the switch and the second filter in each channel can simply be eliminated. If you are unsure of how much high frequency amplification you might need, or in the case where more than one operator may be sharing a station, the switch and the second stages will prove useful. S1 could also be replaced with two switches - one for each channel - if your high frequency hearing is not similar in both ears.

For gain slopes other than 3 dB/octave or 6 dB/octave, one or both filters in either channel can be modified using the equations given earlier. Taking this further, one or both of the op amps in either channel do not have to be shelving filters — they can be used to implement a variety of other filter functions including notching, peaking, or multi-pole functions. Op-amp filter design is covered

extensively in circuit design handbooks and on the Internet.

In addition to tailoring the gain change versus frequency, the overall gain of each channel can be adjusted to compensate for the sensitivity differences between ears. Overall gain is adjusted by changing the voltage dividers R7+R8 and R17+R18. R8 and R18 can also be replaced with 5-k Ω potentiometers if adjustable gain is desired.

When considering changing the design, it's important to know that human speech recognition is remarkably tolerant of deviations from an ideal amplitude versus frequency response curve. Also, personal preference comes into play — you may hear more comfortably with less than complete compensation for high frequency hearing loss. Although 6 dB/octave compensation closely matches the author's hearing loss, he

usually has the AIE switched to 3 dB/octave compensation. At this setting, intelligibility is improved considerably.

CONSTRUCTION

With a few exceptions, the layout of the component parts is not critical. The leads on the IC power decoupling capacitors (C22, C23, C24) and all leads to the op amp inputs should be kept as short as possible. Be sure

to make the U1 power connections at pins 4 and 11.

The completed AIE is shown in **Figures 61** and **62**. The prototype is built on a grid style PC board with 0.1 inch centers cut to fit snugly in a 6×2×1 inch plastic project box. Parts numbers for the PC board and the project box are included in the parts list. A PC board is available from FAR Circuits (**www.farcircuits.net**).

Two cautions are in order. First, building an AIE as small as the prototype requires small tools, a large magnifying glass and patience. Since the circuit design is not particularly sensitive to layout, consider using a larger layout and a larger enclosure. The second caution is with regard to using a plastic enclosure. Susceptibility to RFI and 60 Hz hum pickup will be greatly reduced by using a metal enclosure. If you have lots of RF in your shack you may have no choice but to use a metal enclosure.

Components are readily available from online suppliers such as Mouser or DigiKey. Several substitutions can be made if needed. The $1.33\text{-}k\Omega$ resistors can be made from a $1\text{-}k\Omega$ and a $330\,\Omega$ resistor in series; the $6.65\text{-}k\Omega$ resistors can be made from two $3.3\text{-}k\Omega$ resistors in series, and the $1.5\text{-}k\Omega$ resistor can be made from a $1\text{-}k\Omega$ and a $470\,\Omega$ resistor in series. The value of the $0.0015~\mu\text{F}$ feedback capacitors is not critical (C3, C5, C12, C14) — $0.001~\mu\text{F}$ disk ceramics can be substituted.

HOW WELL DOES IT WORK?

Intelligibility is absolutely crucial to maintaining high QSO rates and correct logging in contests, and in pulling the weak ones out of the noise when DXing or operating in less-than-ideal conditions. The AIE has provided the author with an immense improvement in both activities. It's just as helpful for reducing listening fatigue during ragchewing or general listening as well.

A real surprise was how much intelligibility improved on CW. This may seem counterintuitive at first, if you view "continuous wave" as comprising a single frequency. From a communications standpoint, however, the CW waveform is not continuous — it is comprised of elements - dots and dashes. The leading and trailing edges of each element are made up of frequencies higher than the carrier frequency, and hearing these helps the listener separate one element from the next. When the rise and/or fall times of the elements are very fast compared to the carrier frequency, the high frequency content of the waveform becomes sufficiently large to cause key clicks. Very slow rise and/or fall times produce the opposite of clicks — a sound that experienced CW operators describe as "mushy."

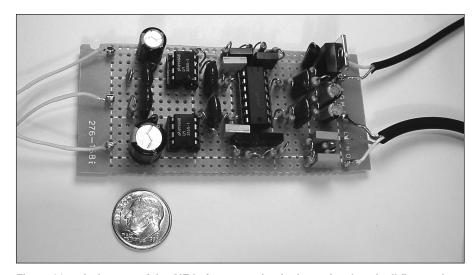

Figure 61 — A close-up of the AIE before mounting in the project box. It all fits neatly within a $6\times2\times1$ inch enclosure if you have the patience to build within tight spaces.

Figure 62 — The AIE takes up little desk space. It plugs inline between the transceiver and headphones and requires 13.6 V dc. In the author's shack, the unit is powered from a transceiver accessory jack and is always switched on.

Mushy code is very difficult to copy, particularly at high speeds, because the ability to decipher when an element has started or stopped has been reduced. Degraded high frequency hearing has the same detrimental effect on CW intelligibility as slowing down the waveform edges — it makes a properly formed CW waveform sound mushy. The AIE restores perception of the waveform edges in CW, just as it does for speech.

How much an AIE or any other approach to compensating for your hearing deficiencies will help you depends, to a large degree, on the state of your hearing. The more you have lost, the more you have to gain back. Audio shaping may also offer some intelligibility improvement if your hearing is within normal limits. Typical receiver bandwidths are narrower than the audio range needed to fully support intelligibility

— some of this can be gained back with high frequency amplification.

One cautionary note from Jim Collins, N9FAY, a designer in the hearing aid industry. At low volume levels, a device such as the AIE is helpful in improving intelligibility. At high volume levels, the audio will start to sound "tinny." This happens because as sound levels increase, the corrective frequency curve must flatten. At upper sound levels of comfortable hearing, it becomes almost a flat line with unity gain, In other words, the hearing response is close to normal at high sound levels. If a device like the AIE is used for prolonged periods at high volume levels, it may accelerate hearing loss at upper frequencies. For more discussion, see Technical Correspondence in May 2005 QST, p 70.

15 An Audio Interface Unit for Field Day and Contesting

For Field Day and multioperator contest operation, it's sometimes desirable for a logger or observer to listen to a transceiver in addition to the main operator. The project shown in **Figure 63**, by John Raydo, KØIZ, makes two-person operation more efficient. Dual stereo headphone jacks, volume controls and an external speaker jack are provided, as well as jacks for both dynamic and electret microphones and an intercom feature for operator and logger to more easily communicate via headset mics.

There are times when the operator and logger need to talk to each other, for example to resolve a call-sign ambiguity. With this unit the operator can initiate two-way intercom communication by closing an intercom switch. The logger, however, can only initiate one-way intercom to the operator. This is so that the logger can't inadvertently cut off the operator during a contact. To respond, the operator closes his intercom switch. In both instances, radio volume is reduced for "talk-over" during intercom use.

Both the operator and logger need headsets with microphones. The unit has two intercom switches plus jacks for optional foot switches for hands-free operation. Here's how it works:

Operator communicating with the logger: The operator presses and holds the OPERATOR TALK switch (S3 on the unit or by using a foot switch connected to J4). This disconnects the operator mic from radio. Both mics are connected via an internal amplifier to both headphones. Radio volume is reduced (adjustable using the RADIO VOL control). Operator and logger can talk to each other.

Logger communicating with the operator: The logger presses and holds the LOGGERTALK switch (S4 on the unit or by using a foot switch connected to J5). Logger mic is connected via an internal amplifier to both headphones. Operator mic remains connected to radio and can still transmit on the radio. Radio volume is reduced. The operator can respond to the logger by pressing the OPERATORTALK switch.

CIRCUIT DESCRIPTION

The circuit diagram shown in **Figure 64** is designed for use with dynamic microphones such as the HC4 and HC5 elements used in various Heil headsets, or for Heil iC type headsets that use an electret element. The electret mic jacks supply the required dc for that type microphone. Mic bias current is limited to less than 1 mA to avoid damage if a dynamic mic is accidentally plugged into the wrong jack. The higher electret output is reduced by resistors R11 and R28.

Both mics have preamplifiers with 34 dB gain set by the ratio of the resistors R4/R3 and R9/R8. The INTERCOM volume controls, R14 and R15, allow operator and logger to individually adjust their intercom volumes. The preamps feed a single 2-W intercom amplifier.

Closing the OPERATOR TALK switch transfers the operator mic from radio to intercom preamp and amplifier via K1 and then to the headphones via K2. Pressing the LOGGERTALK switch will also activate K2 (but not K1). During intercom use, audio from the radio passes through control R20 (RADIO VOL) at reduced volume. S2 (L+R) allows selection of both

Figure 63 — Front view of the audio interface box. Operator controls are on the left and logger controls are on the right.

left and right sides of the headphones or only the right side, for the intercom. The operator and logger each have individual headphone PHONE VOL controls R24 and R25 (the operator control also incorporates the POWER switch, S1).

CONSTRUCTION

The unit shown is built in a PacTec plastic box. The front panel has the control switches and volume controls described in the previous section. The back panel (**Figure 65**) has $\frac{1}{4}$ -inch stereo jacks for two pairs of headphones, two 3.5-mm mono jacks for headset microphones, 3.5-mm stereo and mono jacks for connection to the radio's headphone and mic jacks, one stereo 3.5-mm jack for a speaker, two 3.5-mm mono jacks for foot switches and a jack for a 9-V power supply (a wall wart is okay). A 12-V dc supply can be substituted if K1 and K2 are changed to 12-V units and the LED series resistors R22 and R23 are changed to $1 \text{ k}\Omega$.

Other than controls and jacks, most components are mounted on a prototype circuit board supported by four ½ inch spacers and shown in the box in **Figure 66**. A suggested parts layout is shown in **Figure 67**. Point-to-point wiring is used between circuit board pads and is not particularly critical. A PC board for this project has been developed by FAR Circuits (www.farcircuits.net).

Connections to both mic jacks and the radio mic jack use shielded cable to reduce hum and risk of interference pickup. Connect the shields on the operator and radio mic cables to a common ground point on the circuit board near U1. Bypass capacitors C8, C9 and C16 and resistor R6 are mounted at their respective jacks. Rub-on lettering, followed by a couple light coats of clear plastic spray, helps give a professional appearance.

Connecting an external speaker in addition to two headphones might be too much of a load for some radios and cause reduced volume and/or distortion. Try an inexpensive amplified computer speaker plugged into the audio interface external speaker jack to reduce the load.

You will need two cables to connect the unit to your radio. A 3.5 mm mono plug-to-plug shielded cable for the mic circuit is compatible with a Heil headset mic. A 3.5 mm stereo plug-to-plug cable works for the earphones.

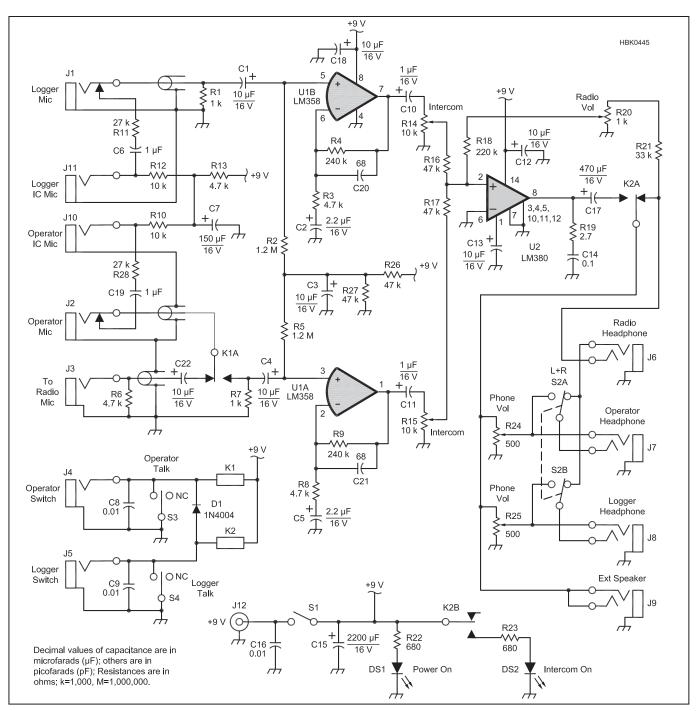

Figure 64 — Schematic diagram and parts list for the audio interface unit. Mouser parts are available at www.mouser.com. Resistors are ½ W unless notes (¼ W are fine too.) A PC board is available from FAR Circuits (www.farcircuits.net).

16 Two QSK Controllers for Amplifiers

Many CW operators feel that QSK—or full break-in—operation is the most natural and conversational way to operate. "Full" break-in switches between transmit and receive so quickly that the operator can hear anything happening on the channel between individual code element dots and dashes. (Semi break-in uses a VOX-like circuit, remaining in transmit until a delay timer expires.) That sense of transparency enables the operator to respond immediately to interference or requests from other stations. Originally developed in support of high-speed CW traffic passing, QSK today is most often used by contest operators and for high-speed ragchews.

For low-power operation at 100 to 200 W, QSK circuits can use relatively small relays or solid-state PIN diode switches. However, when an amplifier is used, the requirements for voltage and current-handling go up dramatically. This leads, in turn, to the use of vacuum relays and high-power PIN diodes. *Hot-switching* — opening or closing mechanical contacts during current flow — greatly accelerates wear and can even destroy the relay contacts. Preventing hot-switching requires strict timing and interlock design to make sure the proper sequence of switching-then-transmitting occurs every time.

QSK controllers generally fall into one

of two general types: hardware-only, in which the timing and logic of the sequential operations are built-in to a hard-wired circuit, and software, in which the switching circuits are under the control of a microprocessor. This pair of QSK controllers includes one from each camp: Jim Colville, W7RY, designed an analog controller and Paul Christensen, W9AC, programmed an Arduino processor for his controller. You can choose to implement whichever project you feel most comfortable with. We'll begin with an overview of QSK operation by W7RY and then present both projects.

SAFETY

Should you decide to add QSK to your amplifier, you'll be working inside the amplifier. Safety is the top priority in working on any equipment that contains high voltage, such as a vacuum tube amplifier. The shorting straps and interlocks are there for your safety, please respect them and be very careful! Read and follow the recommendations of the High Voltage Techniques section of the **Power Sources** chapter and the **Safety** chapter of this book.

Also be sure to operate the amplifier with all shields in place. You don't want to exceed the MPE (maximum permissible exposure) of RF energy to your body. And you just never know when the cat is going to jump up on your workbench!

BASIC QSK PRINCIPLES

How is QSK different from PTT or semi-VOX operation in an amplifier? When switching is controlled by manual use of a PTT switch, the amplifier relays are usually energized long before the RF is output by the transmitter. With semi break-in, the receive/transmit transitions are usually between words or syllables rather than between dots and dashes.

Several things have to happen quite quickly with QSK, especially when you're sending CW at 30 WPM!

- 1. Switch the amplifying device bias from cutoff to the proper operating bias setting in less than 2 milliseconds.
- 2. Switch the RF relays from the bypass mode (in which the transceiver is connected directly to the antenna and the amplifier is biased OFF) to the transmit mode (in which the antenna is connected to the amplifier output and the transceiver is connected to the amplifier input). This must happen before

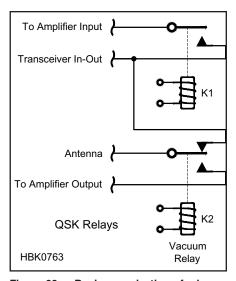

Figure 68 — Basic organization of relay switching for QSK.

RF starts flowing from the transceiver into the amplifier. (We are assuming the use of a modern transceiver for the remainder of this discussion. The same principles apply in switching separate receiver-transmitters.)

Figure 68 shows the basic relay wiring for a OSK system.

This design uses only a single-throw relay for routing transmitter output to the amplifier input. Using a double-throw relay with another contact for receive adds another opportunity for the contacts to become intermittent in the receive path. Henry Radio used the approach of Figure 68 for all of their later production runs of amplifiers. Relay contact materials that are rated for transmitter output levels can become intermittent at the extremely low levels of received signals.

Basic Timing Considerations

When the key or keyer paddle is pressed, several things happen in the transceiver. First, the key or paddle state must be read by the rig's keyer or microprocessor. The transceiver then switches into transmit mode, which mutes the receiver, switches the amplifier keying circuit, and starts to output RF. Most modern transceivers have the option (usually a menu selection) for either a mechanical relay or FET amplifier keying circuit.

Proper QSK operation depends on the delay between when the transceiver's linear amplifier keying relay energizes (after contact bounce has stopped) and when the radio starts to transmit RF. This delay, which is easily measured, is the key element in control of linear amplifier antenna relay and bias switching. The author has measured many modern transceivers such as the ICOM IC-7600, IC-751A, IC-7200, IC-756 PRO-II, and IC-756 PRO-III. All of these transceivers typically have a delay from final contact closure to RF output of about 4 to 6 milliseconds, shown for the IC-7200 in Figure 69. (The IC-751 A is actually adjustable with an internal control.) The timing in SSB and RTTY seems to follow the CW timing in most radios.

The same process works in reverse when going from transmit to receive. RF output stops, the amplifier switching circuit changes back to receive, and the receiver is un-muted. This delay is typically a bit longer and **Figure 70** shows the IC-7200 delay, measured at about 6 ms.

If PIN diodes are used for switching the RF, speed is generally not an issue as the diodes switch in microseconds. If electromechanical relays are used, however, the few milliseconds available when going from receive to transmit require a fast relay. Reed relays are typically used for low power, such as the output of the transceiver, and are fast enough to use for QSK. Higher power, high-speed

vacuum relays must be used at the amplifier output. These relays open and close in around 1 ms and are rated for millions of open-close cycles.

All mechanical relays and switches have contact bounce because of flexing in the relay's moving armature. Contact bounce is clearly visible with an oscilloscope when measuring the time it takes for a relay to close or open. All of the measurements in this article include the contact bounce time until the contacts are ready for power. A more detailed discussion of modifications to speed up the relay circuits is available in the PDF article "W7RY QSK Relay Timing" also included with the downloadable supplemental content.

Proper control of switching timing has benefits other than operational convenience. As W7RY relates, "After adding QSK to a Drake L-4, a Kenwood TL-922, and a Heathkit SB-200, the pesky arcing in the tuning capacitor stopped. The TL-922 was especially prone to it and the Heathkit SB-200 did it quite often when I was checking out the amplifier after I had purchased it. What happened?

"The arcing stopped because the amplifier was no longer hot-switching the relays and

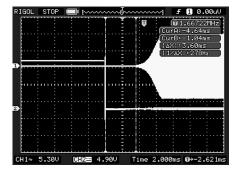

Figure 69 — The relay-close-to-RF timing for an ICOM IC-7200. RF output appears 3.6 ms after the amplifier relay contacts close. The relay-to-RF time can be increased 1.5-2.0 ms by substituting a small switching transistor for the relay.

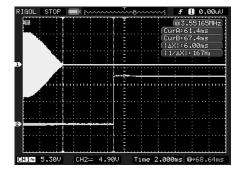

Figure 70 — The same ICOM IC-7200 timing from RF-stop to relay contacts open. There is 6 ms between the end of the RF output and the relays returning to receive.

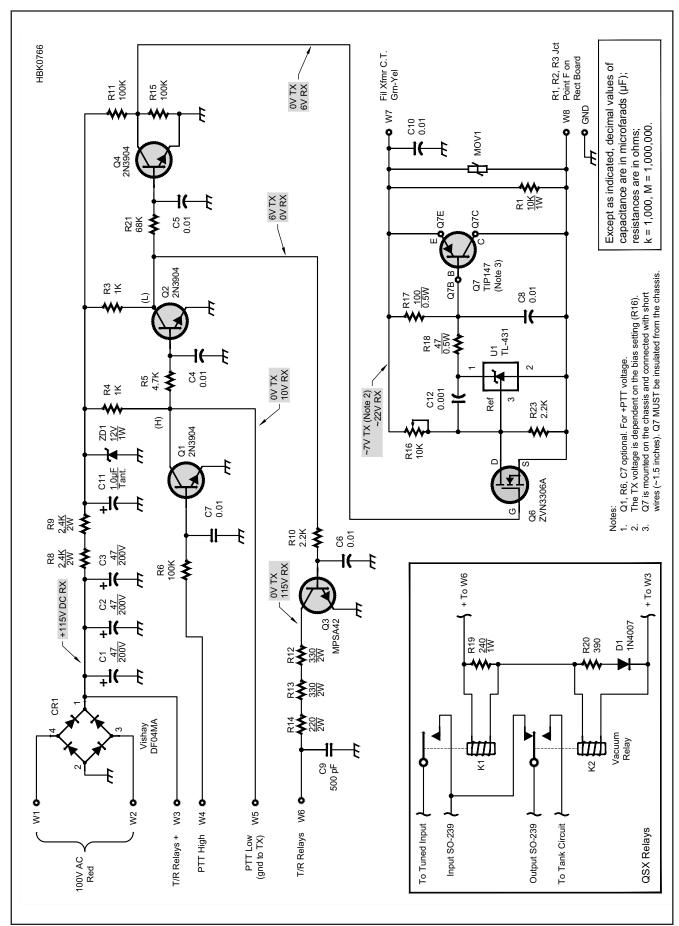

Figure 71 — The schematic for the SB-220 QSK controller. A PC board layout and parts list may be found with the onine supplemental content.

applying RF drive before the output of the amplifier was transferred to the antenna system! The Kenwood TL-922 has two huge, slow and loud antenna change-over and bias switching relays. With those s-l-o-w relays, the RF drive was getting to the tubes before the output relay contacts had switched! It was that simple. The Drake had arced in the tuning capacitor at least once. Now, it's smooth as silk. I used my TL-922 with QSK in the 2012 and 2013 ARRL RTTY Roundup contests and it worked perfectly! No arcs or sparks in the entire 30 hour contest on 10, 15 and 20 meters."

Note that properly designed QSK systems prevent hot-switching of the relays and possible arcing in the output tuning network whether full QSK is used or not. This will reduce wear of the relays and stress on the amplifier, leading to more reliable operation.

Tube Bias Control

In a vacuum tube linear amplifier, the QSK circuit must switch the tube's cathode-to-grid bias from cutoff in receive to a resting-current condition in preparation for transmit at the same rate as the antenna relays. The cutoff bias voltage must achieve the ZSAC (Zero Signal Anode Current, a.k.a. idling current) as stated by the tube manufacturer. For most 3-500Z amplifiers using ~3200 V, this voltage needs to be between 6 and 8 V.

Components and Construction for QSK

Placement of the relays in the amplifier isn't critical, but installing the relays near the input and output connectors is usually the most convenient and keeps leads short. Relay mounting isn't critical except for keeping them quiet. The author recommends mounting the relay on a rubber grommet through a hole or on a "bed" of silicone glue/sealant. Lead connection has a lot to do with keeping the relays quiet. The shield braid of RG-174 coax works well to absorb vibration. Just make sure you don't get the braid full of solder, or the extra stiffness defeats the purpose. Bend the braid into a fairly large horseshoe shape and solder to the relay terminals, and then solder either to the RF connector directly or to the coax that connects the other circuitry.

Reed relays have glass-encapsulated contacts in a vacuum and a coil wound around the outside of that glass housing. The reed doesn't have to travel very far to make contact so the relay is extremely fast: closing is measured at less than 700 μs (0.7 ms) and opening slightly faster, on the order of 500 μs or less. A contact rating of 1 to 2 A is sufficient for 100 W or less of drive. Because of the speed, relay coil voltage is not critical. A resistor across the coil can compensate for higher or lower coil voltage and current. A 12 V coil reed relay is recommended.

Remember that when the amplifier is turned off or bypassed, the transmitter output RF doesn't pass through the reed relay. You can use a small mechanical relay, but they are slightly slower than a reed relay and are also noisier. Be cautious with the mounting and lead connections to keep the "sounding board" effect to a minimum.

The amplifier output vacuum relay must be of the smaller type such as the Jennings RJ1A, Kilovac HC1, Gigivac GH1, and the generic VHC-1. The Jennings RF1 style is just too slow, as are any of the glass-envelope vacuum relays. Do not use an HC3 or VHC-3 type of relay because they are rated only for dc, not RF.

The RJ1A relay's specified close time is 6 ms. Measurements show a typical closure time of about 3 ms. By using a higher initial voltage, the closure time can be reduced to as little as 1.5 ms, but the average time is around 2 ms.

The relay's release time depends on the relay coil's kickback suppression circuit. The usual circuit is a reversed-biased diode connected across the coil. A resistor in series with the diode dissipates some of the energy in the coil and helps release the relay armature more quickly.

W7RY — Analog QSK Controllers

This project is really a series of controllers developed by W7RY for several popular non-QSK amplifier models. The SB-220 QSK controller shown in will be summarized as a design example — the schematic is shown in **Figure 71**. Additional construction details for the SB-220 controller are available with the downloadable supplemental content. Design information for the Heathkit SB-200 and the Kenwood TL-922 QSK controllers are also included as separate packages of files.

The goal was to design a board that would be easy to install by anyone with electronics background with little to no support. The other requirement was little to no addition of major components to the amplifier. With the varieties of boards that the author designed, there is probably a board to fit most any amplifier. (See W7RY's web page www.qrz.com/db/W7RY for more information on these designs.)

As you may know, some older linear amplifiers used a fairly high voltage to switch the transmit-receive relay(s). Solid-state transceivers then had to use an external relay, which added even more delay to an already slow switching system, or install an aftermarket soft-key module into the amplifier.

The controllers use low voltage switching signals so that no additional power or interface

signals are required. There is also a positive voltage input switching line if the available amplifier keying signal is positive-going. Some radios have a very fast positive-going keying signal that is even faster switching than the grounded amplifier relay switching signal. If the amplifier switching relay is a bit slow in your particular transceiver, you might be able to use a positive voltage to key the amplifier.

W9AC Universal Sequential QSK (S-QSK) Controller

The Universal S-QSK (S-QSK) board (Figure 72) is designed to control many RF switching applications, all controlled by an onboard Arduino Nano or PIC microcontroller. Through a choice of microcontroller programs, one S-QSK board can manage many different types of switching functions. Sample code, line-by-line documentation, and structured flowcharts are provided to assist the novice programmer with code customization. Structured logic is used for easy code modification. Copy and paste the source code into the Arduino software's edit window, then upload to the Nano board with a mini USB cable.

Presently, three programs have been written for S-QSK: an amplifier QSK controller; a TR switch for separate receiver-transmitter combinations, and a protection circuit for receiver inputs. (The latter two applications are discussed in the full version of this article with the downloadable supplemental content.) When used as a QSK controller, S-QSK is designed to be used with the user's choice of external RF relays or a PIN diode switch. Circuit boards to support PIN diode TR switching and remote outputs that will interface with S-QSK's headers are being developed by the author.

The schematic of the S-QSK is shown in **Figure 73**. A complete parts list, PCB layout drawings, flow charts, and C++ source code are additionally provided with the downloadable supplemental content. In addition, a double-sided professionally-made PCB is available from the author via his website at **www.qrz.com/db/w9ac**. Updates and revision information will also be made available on the same web page.

A powerful attribute of the Arduino microcontrollers is that they come preprogrammed with a bootloader, allowing the user to quickly upload new C++ code without the use of an external hardware programmer that is commonly needed for PIC and EEPROM chips. Connect a mini-USB cable to a PC USB port and you're ready to program. Optionally, the user can bypass the bootloader and program the microcontroller through the ICSP (In-Circuit Serial Programming) header.

The microcontroller and peripheral circuits

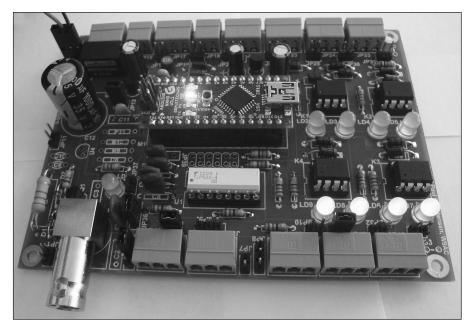

Figure 72 — The S-QSK board showing the Arduino microprocessor and the LED error indicators. The RF SENSE input connector is at the lower left. [Paul Christensen, W9AC, photo]

are powered by the USB port during testing, and an external +7 to +12 V supply powers S-QSK during normal operation.

S-QSK FEATURE SET

A common hardware platform is used to implement many applications where precise timing is required between switching events. The hardware remains the same; only the source code changes for different applications.

- An Arduino Nano or PIC microcontroller plugs into the S-QSK motherboard. Programming a Nano requires no special hardware—code is uploaded via a USB cable from the host PC. For advanced programmers, a 16F88 PIC chip can be used in place of the Nano.
- Uses screw-down Phoenix-style I/O connectors. Each I/O connector can be unplugged from the motherboard for easy assembly and servicing.
- Four digital input channels; eight digital output channels. Header for access to optional analog channels.
- Optically isolated I/O for maximum RFI immunity. Photo-Darlington transistors on the input and solid-state PhotoMOS relays on the output.
- Each input channel can be selected for dry contact closure, fed from a solid-state open collector or any other solid-state switching device.
- Each output channel can be selected to float or reference circuit ground. Each output can be jumper-selected to function as a current sink or current source.

- RF sampling via BNC connector or 2-pin header. RF is converted to a dc level and conditioned to drive photo-coupler. RF sensing activates with less than 100 mW of RF power.
- Remote RF sensor board can be used to sample RF at a distant location or where a T RF connection presents an unacceptable line mismatch.
- On-board LED diagnostic status indicators on all output lines.
- Uses a +12 V dc-dc converter, bootstrapped to the +12 V supply to provide +24 V for vacuum relays.
- Two optional, jumper-selected relay coil accelerators.
- Board can be populated with only the circuits of interest, thereby saving on construction cost and assembly time.
- Precise control and delay of all steps in 1 ms timing increments.
- Significant hot-switch fault protection built into the code. Before anything can switch between steps, RF is first sampled and judged with the state of the input key line.
- Small board size: S-QSK measures 4.5 × 3.5 inches. The remote RF sensor is 1.7 × 1.6 inches.

S-QSK OPERATION

S-QSK precisely sequences all critical timing elements between an RF power amplifier and transmitter/transceiver. The S-QSK board will work with QSK and non-QSK amplifiers. A sequenced electronic bias switching (EBS) system is created and

supports both two-state and three-state bias control. Switching between types only requires a simple change to the microcontroller code.

The delay time between events is independently adjustable to accommodate various transmitter and amplifier timing characteristics. The input key and RF sensing lines are polled in a loop. Depending on the line states and the state of a flag bit, the S-QSK board's output key line, solid-state relays, and bias control are switched with time sequencing to avoid "hot-switch" effects. (See the flow chart files provided with the source code.)

S-QSK offers hot-switch RF protection by sampling the presence of the complete RF envelope. If RF excitation is present at the input to the S-QSK board before the input key line is active, a switch from receive to transmit is inhibited. Likewise, if the RF envelope has not decayed to zero after transmission, the S-OSK board will not switch back to receive. If either type of timing fault occurs, one of two LEDs will illuminate, showing a fault. The LEDs remain lighted until the timing fault clears. Each LED is pulsed to remain on for 0.5 second in the event of brief timing faults. Upon detection of a post-switch fault, bias lines are deactivated, providing further amplifier protection.

For three-stage EBS systems, "hang" bias is supported and is adjustable by the user from 0 ms to 255 ms in 1 ms increments.

In addition to establishing precise timing between amplifier switching elements, S-QSK can accelerate the relay activation time of frame-type output and input relays. The board contains two optional relay coil accelerators, each powered by a choice of +12 V or +24 V power buses. The accelerator circuits are engaged with header jumpers. For mechanical TR switching, Jennings RJ-1, Kilovac HC-1, and Gigavac GH-1 are all good choices for the RF output relay when they are powered at their rated supply voltage. For the input relay, consider the Aromat/Matsushita RSD-12V.

An RF input sample is capacitively coupled by C1 from the RF SENSE input connector J1 or JP1 header to a detector circuit consisting of R1-R3, C3, D1-D2 and Q1. RF sampling is optically isolated from the microcontroller digital inputs by a phototransistor in U1. A remote RF sampling board (under development as this edition was being prepared — see the author's website) can also be used in instances where a T RF connection presents an unacceptable line mismatch or where the sample point is at a long distance from the main S-QSK board. The detector circuit will indicate the presence of RF at less than 100 mW of power.

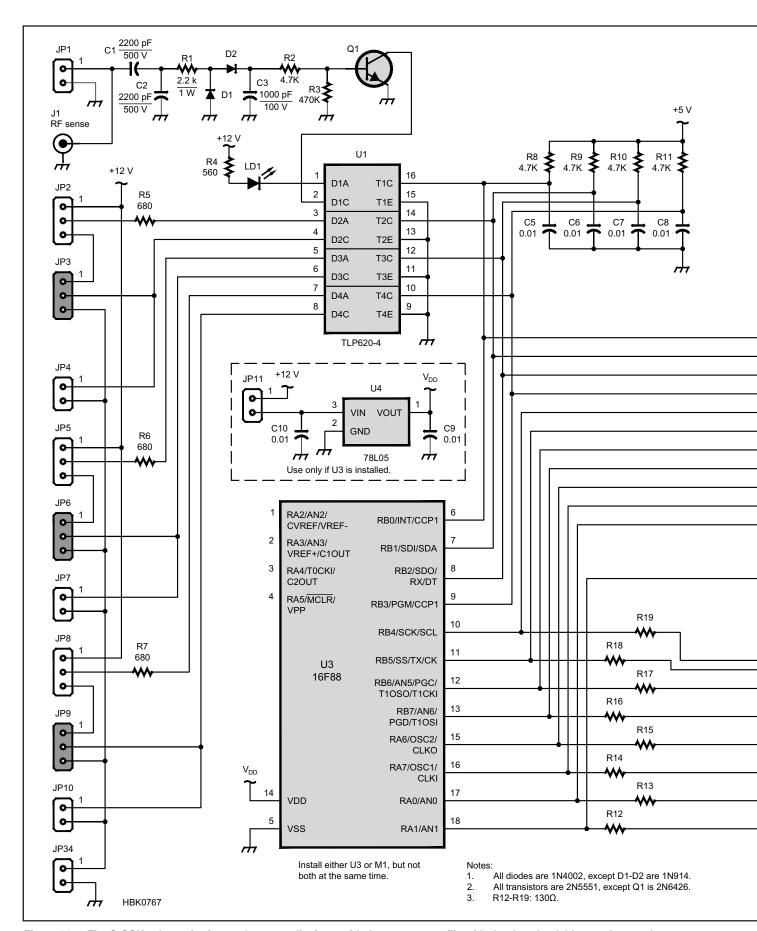

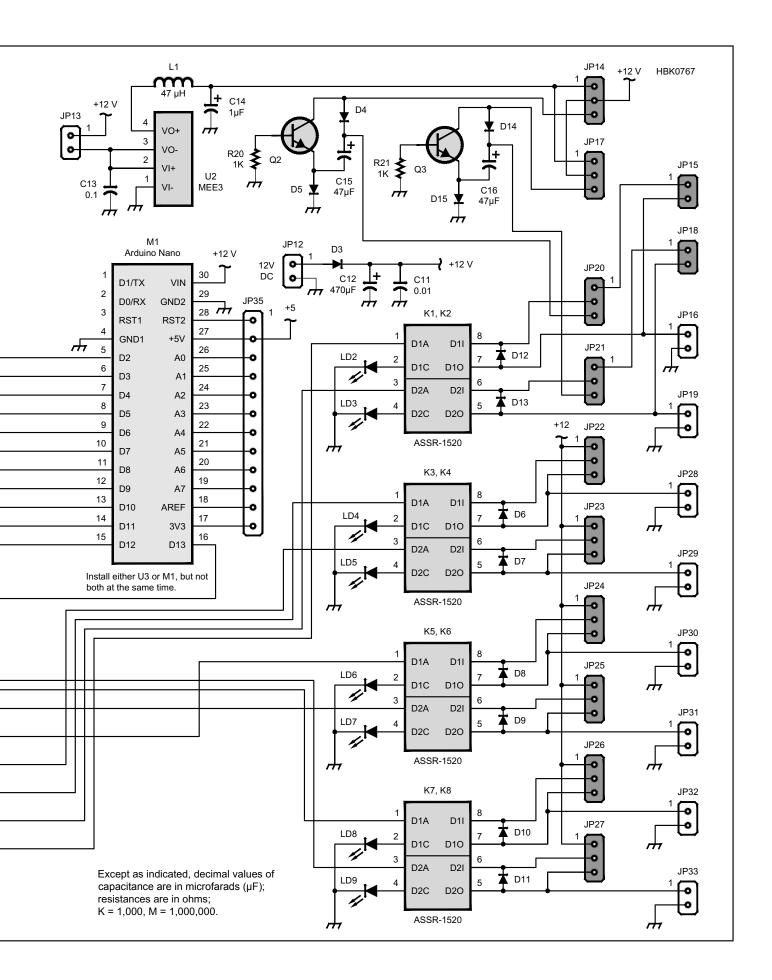

Figure 73 — The S-QSK schematic. A complete parts list is provided as a separate file with the downloadable supplemental content.

17 A Legal-Limit Bias-Tee

The following project by Phil Salas, AD5X, describes a bias-Tee that can be used at full legal-limit power levels from 1.8 to 230 MHz while supplying up to 3 A of dc current. The project was originally published in the January 2013 issue of *QST*. The full article, including all construction details, is available with the downloadable supplemental content. Additional information is available on the author's website at www.ad5x.com/images/Articles/BiasT3amp.pdf.

A bias-Tee enables the supply and extraction of dc power via the center conductor of a co-axial transmission line along a high-isolation inductor. It is used to power remotely located RF switches, preamps, and antenna tuners without a separate dc feed. **Figure 74** shows a typical application in which a pair of bias-Tees power a remote antenna tuner.

BIAS-T DESIGN CONSIDERATIONS

A dc/RF isolating inductor must provide high reactance across the bands of interest while carrying the required dc current with minimal voltage drop. Also the inductor's Q must be high to minimize power dissipation of the RF signal in the inductor. A large number of inductors were characterized using the author's AIMuhf vector network analyzer. Most had multiple resonances across the HF spectrum or the Q was too low.

The J.W. Miller 5240-RC 40 μ H inductor was selected for this design. This inductor is rated to carry 3 A with a typical specified self-resonant frequency of 145 MHz. The choice of inductor is critical to keep impedance high across the entire range of amateur bands through 222 MHz. (The full article with the downloadable supplemental content contains the vector network analyzer data for this inductor and the completed bias-Tee with the 6.8 pF compensation capacitors.)

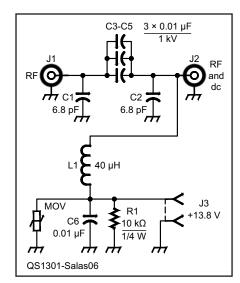

Figure 75 — Schematic of the bias-Tee. The series 0.01 μ F capacitors should be physically large to reduce RF losses. The 40 μ H inductor is specifically chosen to present high reactance across the entire operating range (see text).

- (2) #8 stainless-steel flat washers

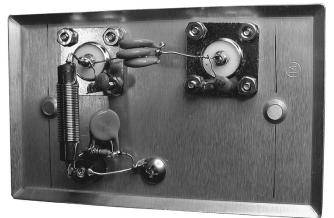

Figure 76 — Internal construction of the bias-Tee, following good RF construction practices.

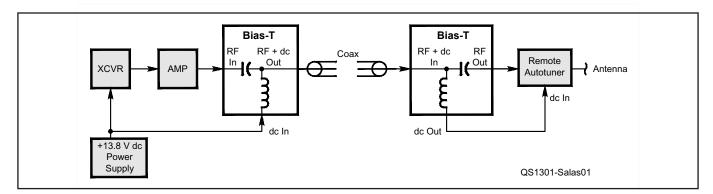

Figure 74 — Typical application of a bias-Tee in an RF system. The same bias-Tee design is used for supplying and extracting dc power.

BIAS-T CONSTRUCTION

Figure 75 shows the schematic and parts list for the finished unit, including mechanical parts. The bias-Tee was constructed in an inexpensive outdoor electrical cast-aluminum box. Figure 76 shows the inside of the finished unit. (See the full article with the downloadable supplemental content for a photo of the completely assembled unit and mechanical layout drawings.) A handwired assembly like this bias-Tee requires

good RF construction practices with direct connections made with short leads if the full range of operation at VHF is to be realized.

All components are mounted on the outlet box cover. The mounting hardware is stainless-steel for outdoor use (the cover includes a weatherproof gasket). The three $0.01~\mu F$, 1~kV parallel capacitors were not chosen for their voltage rating as there should be virtually no RF voltage drop across them. However, physically large capacitors are required to

reduce power dissipation from the high RF current through them at legal limit operation (approximately 5.5 A RMS for a 50Ω load).

In the dc in/out section, an MOV provides transient protection for voltages greater than about 18 V dc and the 0.01 μF capacitor provides RF bypassing. A 10 $k\Omega$ resistor provides a dc path to ground — this prevents static buildup when the dc in/out connection is not present or disconnected.

18 An Eight-Channel Remote-Control Antenna Switch

(Another remote antenna switch project from previous editions, "A Low-Cost Remote Antenna Switch" by Bill Smith, KO4NR, is included with the downloadable supplemental content.)

This project is a remotely-controlled antenna switch designed by Michael Dzado, ACØHB. It allows the selection of one of eight antennas or can be used to feed one antenna to any of up to eight radios. The complete system consists of a remote switch assembly (shown in **Figure 77**) and a selector control assembly. The switch can be used with a control cable, but any solution that provides logic-level control signals to the switch assembly can also work.

The switch assembly's printed circuit board (PCB) was designed to match 50 Ω feed line and maintain a high port-to-port isolation of 70 dB through 50 MHz. The original article with full construction details and test measurements was published in the March/April 2014 issue of QEX magazine and is included as a PDF article with the downloadable supplemental content. Parts lists, PCB layout images, build instructions, kits of parts, ready-to-build PCBs, and additional design details are available from the author at www.ac0hb.com/RF-Switch_Description.

DESIGN DETAILS

The remote control antenna selector system consists of a remote controller assembly and an RF switch assembly.

The remote controller assembly shown in **Figure 78** was designed as a simple solution for the author's station. The assembly consists of an eight position rotary switch and an 8-to-3 digital encoder connected to 2N2222A transistors that drive the RF switch assembly via a standard CAT-5 eight wire cable.

The RF switch assembly contains the relays and relay drive circuitry to select between

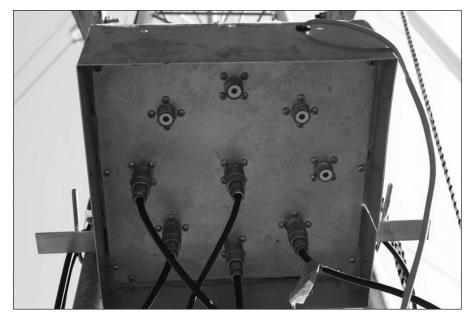

Figure 77 — The remote antenna selector board mounted on a tower, selecting among four antennas.

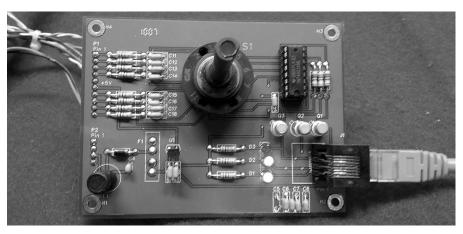

Figure 78 — The antenna selector system's remote controller printed circuit board.

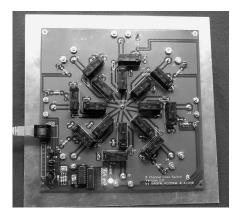

Figure 79 — The printed circuit board for the antenna switch showing the relays and trace layout. Note the symmetrical layout of the switch.

position 0 to 7. The assembly requires only a 13.8 V dc supply and a 3-bit TTL (digital logic) signal as the input for switch position selection. This interface allows for a variety of remote control solutions. **Figure 79** shows the top view of the assembly. The switch control logic incorporates a simple 3-to-8 decoder (74HC238) and a high current, eight-pair Darlington transistor array (ULM2008A) to provide the relay drive current.

High isolation and impedance matching in the RF switch assembly were achieved through several design techniques: Two relays were used in each signal path to doubly isolate the antenna from the radio input. The traces that make up the RF path were designed as a coplanar waveguide. The RF connector placement on the circuit board was tightly controlled to be symmetrical to make the RF electrical paths identical. RF trace routing followed good design practices by limiting angles to 45°. Control traces were routed on the bottom of the circuit board to maximize ground plane continuity. Control trace widths of 15 mils (0.015 inch) were used for better current capacity.

To minimize RF coupling between antenna channels, it was essential to follow the rules and principles of good basic RF/microwave design. The switch assembly features a co-

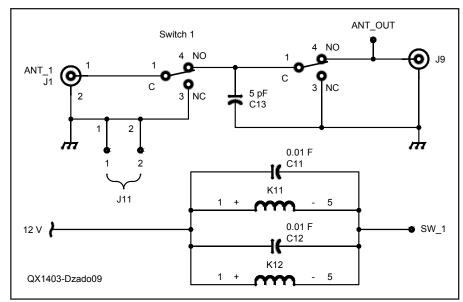

Figure 80 —The schematic of one section of the antenna switch — this section is repeated eight times. When the antenna is not selected, the normally closed contact of Switch 1 grounds the antenna and the second relay disconnects the common antenna port, J9.

planar waveguide for all RF traces, designed for $50\,\Omega$ impedance with ground plane stitching that ensures maximum isolation between ports. Complete impedance (Z_0) matching ($50\,\Omega$ in to $50\,\Omega$ line to $50\,\Omega$ out) minimizes return loss and SWR. A coplanar waveguide design was chosen so that the trace impedance on the circuit board could be matched to the input and output impedances. In a coplanar waveguide design, Z_0 is a function of signal conductor width and thickness and a function of the dielectric constant ($\varepsilon_{\rm r}$) of the material surrounding the signal conductors.

Signal return currents follow the path of least impedance. In high frequency circuits this equates to the path of least inductance. Stitching the ground planes with vias every 0.1 inch or so around each RF trace helps minimize the inductance in the signal return path by virtually creating a waveguide on the circuit board.

The RF connectors were placed symmetrically around the output connector (located in

the center of the assembly) to ensure an equal electrical length for each RF path. Typical isolation measured between ports is greater than 70 dB.

Extensive RF decoupling on the power and control lines was added to provide maximum RF decoupling from the control signals. Transient-voltage-suppression diodes (Transorbs) were added to all input control lines for good surge protection.

The switching relay is at the heart of this design — an Omron Electronics Inc G6RN-1-DC12, which is a sealed double pole, double throw (DPDT) relay with 8 A silver over gold contacts. The contact capacity is more than adequate for our design. We chose to doubly isolate each RF port by using two relays in each path. As shown in **Figure 80**, the first relay grounds the antenna input when de-energized. The second relay simply disconnects the RF port from the output. This schematic is repeated for each of the eight selectable antennas.

19 Digital Audio PTT Interface

This circuit from the November 2016 issue of *QST* was developed by Julian Moss, G4ILO (SK — www.g4ilo.com) for digital operation with a computer sound card. It uses the sound card audio output signal to key a transmitter's PTT (push-to-talk) input. A USB audio I/O adapter can also be used to generate the audio output signal.

The circuit in **Figure 81** acts as a VOX (voice-operated transmit) circuit that keys the transceiver PTT input whenever it detects transmit audio from the computer. The circuit also provides an adjustable audio output (C2, R1, and R2) for control of transmit audio level. Q1 and the associated components amplify the input audio, C3, D1, D2, and C4 act as a detector to produce a positive dc voltage when input audio is present. The output of the detector turns on Q2 to key the PTT input. Q1 and DS1 indicate when PTT is active.

The original "Eclectic Technology" column from June 2016 *QST* used an inexpensive external USB audio adapter as the audio connection to the PC. If the PC has direct audio input and output connections, those can be used as shown here. The original article is included with this book's downloadable supplemental information.

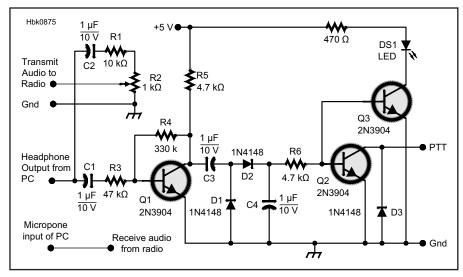

Figure 81 — The G4ILO digital communications interface provides a PTT signal to a transceiver based on transmit audio from the PC. Transmit audio level is adjustable by the interface. Received audio level from the radio is adjusted by the transceiver's audio gain control. Mouser part numbers shown (www.mouser.com).

C1, C2, C3, C4 — 1 μ F ceramic disc capacitors (810-FK24X5R1C105K)
D1, D2, D3 — 1N4148 diodes (512-1N4148)
DS1 — Red LED (78-TLCS5100)
Q1, Q2, Q3 — 2N3904 transistors (610-2N3904)
R1 — 10 $k\Omega$, ¼ W resistor (791-RC1/4-103JB)
R2 — 1 $k\Omega$ potentiometer

(652-PDB181K415K102A2)

R3 — 47 k Ω , ¼ W resistor (791-RC1/4-473JB) R4 — 330 k Ω , ¼ W resistor (791-RC1/4-344JB) R5, R6 — 4.7 k Ω , ¼ W resistors (791-RC1/4-472JB) R7 — 330 Ω , ¼ W resistor (791-RC1/4-331JB)

20 Arduino-Based CW IDer

This project by Bob Anding, AA5OY, was originally published in the January 2017 issue of *QST*. The full article, including programming details, a sketch for the Arduino software, and associated files are included in this book's downloadable supplemental information.

The Arduino microcontroller board is used to generate a CW ID message that is programmable through a PC. The message is initiated by a switch closure which can be mounted on the Arduino assembly or provided by another piece of equipment, such as a timer output. The message content and speed are controlled through the Arduino's sketch software on the host PC

Figure 82 shows the schematic of the CW IDer. An Arduino UNO R3 used for this project includes a USB interface for programming via the Arduino's integrated development environment (IDE). The module comes with a Reset button and a number of general-purpose input/output (GPIO) pins.

When the IDer's activation switch (S1) is

closed, the timer period starts. The number of seconds in the timed interval can range from 0 to 32,000 seconds. At the end of the interval, the PTT LED and Q1 are turned on. The message is then played back through SP1 as an audio tone. A keying output is easily added through Arduino software or by creating a VOX interface (see the Digital Audio PTT Interface project in this chapter).

Figure 82 — The CW IDer uses the Arduino Uno R3 and a handful of parts.

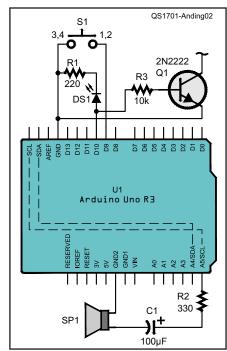

C1 — 100 µF, 25 V electrolytic capacitor.

DS1 — 5 mm red LED.

R1 — 220 Ω , ¼ W resistor.

R2 — 330 Ω , ¼ W resistor. R3 — 10 k Ω , ¼ W resistor.

S1 — Momentary contact switch (N/O).

2019

HF Transceiver Survey

By Joel R. Hallas, W1ZR

As with most major purchases, there is a wide range of choices among transceivers, ranging from the most basic functionality to more bells and whistles than most operators will ever use. As might be expected, advanced features and performance generally go hand-in-hand with advanced prices.

This section considers "all-band" transceivers with 100 W or more output. Although we call them "HF" transceivers, most also cover 160 meters (which is a medium frequency — MF — band). Many also cover 6 meters, some include 2 meters, and a few feature 70 cm and even higher frequency bands. Such wide frequency coverage is a plus for the Technician class operators who start out with limited HF privileges in addition to VHF and above, but may upgrade in the future, or for anyone who wants to explore those bands without resorting to multiple radios. All radios discussed here include a general coverage receiver that tunes at least from the AM broadcast band to 30 MHz, so they can also be used for entertainment, shortwave listening, or even spectrum analysis as well.

The information presented here is current as of mid-2018, but products and prices can change dynamically in such a competitive marketplace. As we write this, several major manufacturers are in the process of updating their product lines. Models may be added, updated, or dropped over time and so the lineup available as you read this may have changed. Check dealer and manufacturer web pages, *QST* ads and Product Reviews (reviews from 1980 on are available to ARRL members at **www.arrl.org/product-review**) as you get close to making a choice.

There are also some nice transceivers available as kits, as well as some that operate at lower power levels. While any of these can provide lots of fun, a new operator may

not be ready for the challenge of low power operation or serious kit building. For radios available either as kits or as factory built, we have shown the factory built prices.

Categories

Transceivers tend to be grouped into a number of categories based on price points and physical configuration. The price is the typical "street price" — representative of the price they sell for at dealers — not the "list price." Prices were approximate, as of early 2018, and subject to change (up or down). Prices do not include any coupons or limited time promotions. Check with your favorite dealer (or manufacturer for those who sell direct) for current pricing — it will be different from the representative pricing shown in the tables. The categories break down as follows:

Entry-level — Desktop transceivers that cost from around \$500 to \$1000. They offer features and performance that cost much more only a few years ago.

Mid-range — Desktop transceivers that cost around \$1000 to \$2000.

Upper mid-range — Desktop transceivers that cost around \$2000 to \$4000.

Top drawer — Transceivers costing \$4000 and up.

Portable and Mobile — Radios that straddle the entry to mid-range prices, but are specifically designed for portable and mobile operation.

Unless otherwise noted, the 100 W radios described are designed to operate from a nominal 13.8 V dc power supply, usually at around 20 to 22 A. The radios at higher power levels tend to have special power supply configurations, often requiring operation from ac mains. Most manufacturers offer a 13.8 V "matching" power supply for the

100 W radios. Aftermarket general purpose power supplies meeting the radio's specifications may also be used.

One of the most active areas of transceiver development is in the application of digital signal processing (DSP) and software-defined radios (SDR). It is worth continuing to educate yourself on these capabilities, as they are displacing a significant number of analog technologies.

Obviously, the assignment of a transceiver to a particular class is somewhat arbitrary and depends on personal tastes and operating requirements. Take the following lists as general assessments and don't be afraid to make your own rankings! In addition, new models and features are continuously introduced. Watch for products announced or reviewed in *QST* and on the manufacturer and dealer websites.

Features of Current Transceivers

Current 100 W (or higher) transceivers tend to include the following features. Some features tend to appear in transceivers of different price ranges, thus the features have been placed in generic groups based generally on price class.

BASIC FEATURES

The following basic features are shared across every category of transceivers. The following is not an exhaustive list but should provide an indication of the benefits of some of the more popular features.

• A general coverage receiver — Typical coverage is from below the medium-wave broadcast band (sometimes lower with reduced sensitivity) to the top of HF, sometimes well into VHF, depending on transceiver frequency coverage. This is also useful

to allow listening to international broadcast stations or other services, as well as the partially authorized LF and VLF amateur bands. It is also very useful as an adjunct to an amateur's workbench as a test instrument.

- Wide transmit frequency coverage All current models extend downward to MF (160 meters) and most extend into VHF with coverage through 6 meters. Some go further into VHF and even UHF. In some cases the additional coverage may reduce or eliminate the need for one or more additional radios in the station, making for a more compact, and sometimes less expensive, station.
- Multiple modes of operation Most current transceivers offer SSB, CW, AM and FM modulation and detection. Most offer provision for digital modes. Depending on frequency coverage, some "HF+" transceivers can also serve as VHF FM transceivers, offering standard repeater frequency offsets, squelch, and tone encoding.
- Choices of selectivity Most current generation transceivers offer DSP-based variable selectivity (filters). In lower-cost models it tends to be a small but usually adequate number of discrete choices, while in higher priced units selectivity is often continuously variable in 50 or 100 Hz steps. Advanced units allow shaping of the passband as well as high- and low-frequency rolloff adjustment. Some offer a dual-passband filter, designed to separately pass each tone of an FSK (radioteletype) signal and not the frequencies between them, thus improving the detection probability in noise or interference.
- Dual VFO operation All current designs offer instant selection of either of two operating frequencies to facilitate split-frequency operation. This allows the setting of one frequency for transmit and another for receive. A single switch or button can be used to toggle between the two so that the transmit frequency can be monitored before transmitting.
- DSP impulse noise and automatic notch filtering Most DSP-equipped transceivers provide for the reduction of impulse noise, such as that from ignition systems or power lines, as well as the elimination of steady interfering carriers.
- CW keyer Most current model transceivers include the capability to connect keyer paddles for sending CW via an internal keyer. Some also include memories to allow one-button transmission of short messages.
- Removable front panel Transceivers designed for mobile operation often have a removable front panel. This allows a compact control head to be mounted near the operator, while the radio's main chassis can be located in the trunk or other out-of-the-way spot.

FEATURES FOUND IN ADVANCED TRANSCEIVERS

More advanced transceivers tend to have additional features for their increased price. Most are larger than the basic units so that the front panels can accommodate additional controls and displays to support the extra features.

- Multiple roofing filter bandwidths Most basic transceivers incorporate a single roofing filter with sufficient width to permit use on all modes. A typical value is 15 to 20 kHz. Improved close-in dynamic range performance for narrower bandwidth modes, such as SSB, CW, and data modes, can be obtained by having narrower roofing filters available to match the transmit bandwidth.
- Adjustable noise blanking Some transceivers include a separate wideband receive channel designed to detect and blank the main receiver in the presence of impulse noise. This capability is often independent of the similar DSP-based function. One or the other may be found to be better at eliminating noise from particular sources, while sometimes using both is even more helpful. Some transceivers offer two separate methods of noise blanking, each suited for different common types of impulse noise.
- Choices of AGC parameters Most transceivers provide automatic AGC settings for different operating modes. Some advanced transceivers provide additional choices to allow optimization for different kinds of operation and different ambient noise levels. For example, to maximize sensitivity for weak signals, the AGC operating threshold should generally be set above the external noise level. This will vary depending on ionospheric conditions. Other parameters include the slope of the AGC curve and hold and attack times.
- Frequency memories Advanced (and some basic) transceivers include the capability to store operating frequencies and other settings in memory. "Band-stacking registers" are multiple memories for each band that are typically accessed by pressing the band selection button multiple times. Typically they will store two or three frequencies per band, along with mode, filter and other settings, in a last-in, first-out register stack.
- Dual receive Some higher-end transceivers include two independent receive channels. Dual receive channels can be useful to monitor two frequencies simultaneously. For example, you could listen simultaneously to transmit and receive frequencies being used by a DX station operating in split mode.

There are some subtle differences between the *sub-receiver* capabilities of different model transceivers. In some transceivers, the sub-receiver can only be used in the same band as the main receiver. This is not a limitation for normal split operation, but it does not permit monitoring a different band for openings or other activity. While some transceivers offer a duplicate receiver system for the sub-receiver, others have sub-receivers with lower dynamic range performance or fewer filter options than the main receiver.

Some sub-receivers have independent antenna input connections that allow operation with two different antennas. If the tuning of the two receivers can be locked together, that can provide a kind of diversity operation to reduce effects of fading. Typically that might entail polarization diversity (one horizontal antenna, one vertical); space diversity with two antennas separated by a wavelength or so; or arrival angle diversity, using horizontal antennas at different heights.

• Panadapter — While a visual view of the received spectrum has been possible for decades with a station accessory called a panadapter, these devices were not too common in amateur stations until manufacturers started building display screens into transceivers. Many current transceivers offer panadapters in different forms. Often they offer views of signals on a band, adjustable over a range from the immediate vicinity of the operating frequency to the whole band.

The display may be a conventional spectrum analyzer-style display with signal displayed as individual peaks, although waterfall displays are becoming more popular. In a waterfall display, signal strength is displayed as intensity or color on sequential frequency range scans. A recent trend is the inclusion of both a panadapter and a waterfall view, in a panafall display. See the **Transceiver Design Topics** chapter in the ARRL Handbook for more about panadapter and waterfall display systems.

Some transceivers with dual receivers provide either dual panadapters or the ability to use one on the second receiver to keep track of band openings while communicating on the main band. In some cases, the receive circuitry is shared with the panadapter so that the audio is disabled during the time of the scan.

A *real-time* panadapter scans the frequency segment and repeats the scan over and over, giving an appearance of continuous updates. Thus newly arrived signals will show up during each scan. Some panadapters offer a single-pass or *one-shot* functionality in which a button press initiates a single scan over the selected range. The display retains the same snapshot of band activity until the next time the button is depressed. While this can provide a sample of band activity, it does

not provide the same level of information as a real-time display.

Some transceivers provide a wideband IF output ahead of roofing filters so that an external panadapter can be used to monitor the received band. The wideband IF output can be used by other external signal processing equipment as well.

- Higher power Transceivers are available at many output power levels, from the very compact and portable low power (QRP) transceivers to medium power radios. While the usual 100 W PEP output transceivers are the most popular, some transceivers provide up to 200 W PEP output or more.
- Audio equalization Long a capability of amateurs interested in broadcast-quality voice signals, many newer transceivers pro-
- vide a DSP-based audio equalization capability similar to professional studio control consoles. This is often available in both transmit and receive. In receive mode, it functions largely as a higher resolution tone control. In transmit mode, equalization can be used to shape audio response to provide higher fidelity. Or it can be used to focus the response to best punch through a DX pileup or compensate for individual voice or microphone response.
- Memory voice recorder Sometimes called a *voice keyer* because of the similarity to a CW memory keyer, this function allows you to record and play back short messages. Voice keyers use digital technology and store the voice signal into memory. Different radios have different numbers of such memories,

and some also can record received audio for playback on the air or to record a contact.

• RTTY and PSK31 decode — Some transceivers, generally at the upper end of the price spectrum, include the capability to decode RTTY and PSK31 transmissions directly on the display screen, eliminating the need for a separate PC and sound card. There usually is a limited amount of screen space for decoded messages, but it is usually plenty for contest exchanges or occasional contacts. A few transceivers provide connections for a computer keyboard to allow sending without an attached PC. The Elecraft K3S provides the capability to generate RTTY or PSK31 encoded data by entering Morse through the keyer paddles.

Entry Level Transceivers

As of early 2018, there are seven radios in full production that fall in or near this category. They include the Alinco DX-SR8T and DX-SR9T, the Icom IC-718, the Kenwood TS-480SAT and the Yaesu FT-450, FT-857D, and now, due to a price reduction, the FTDX-1200. The Kenwood TS-480SAT and the Yaesu FT-857D are marketed as portable/ mobile units, so they are also shown in that category. Radios in the portable and mobile category that fall in this price range may be worth checking out, even if you plan on operating from home. See **Table 1**.

The Alinco DX-SR8T, shown in **Figure 1**, is available at the lowest price of any new 100 W HF radio in any category. It is a very basic radio in terms of its capabilities and options. The DX-SR8T operates on the 160 through 10 meter bands, including the 60 meter channels (as defined at its introduction — there have been some changes since). Modes supported are SSB, CW, AM, and FM with fixed IF bandwidths for each mode including a narrow CW filter. While advertised as a "desktop" transceiver, it does have a removable faceplate, making it worth considering for mobile operation as well.

The Alinco DX-SR9T is similar in capability, appearance and dimensions to the DX-SR8T, but adds an output containing the quadrature (I and Q channel) receive signal components. This can be used to support off-line signal processing in a PC running their *KG-TRX* software-defined radio (SDR) software.

The IC-718, shown in **Figure 2**, was the lowest price entry for some years and is still available, although at a somewhat higher price. It has been around for a while so it doesn't have all the latest digital technology or cover 60 or 6 meters. This radio was produced before IF DSP was common throughout the industry, but it does include an audio DSP add-on module that offers digital noise reduction and a digital notch filter and is now provided as standard equipment.

The operating bandwidth is set via discrete physical filters. A 6 kHz filter for AM and a 2.4 kHz filter for SSB are provided. A single additional slot is provided for optional bandwidth filters. Icom offers a narrower (1.9 kHz) bandwidth SSB filter for about \$250. Other bandwidths for CW and SSB are available from aftermarket sources such as

Table 1
Transceivers in the Entry Level and Portable/Mobile Categories
All are 100 W PEP output transceivers unless otherwise noted.

Entry Level					
Model	Street Price	DSP	60 Meters	V/UHF	Ant Tuner

Kenwood TS-480SAT	\$1100	AF	Yes	6 Meters	Yes
Kenwood TS-480HX**	\$1350	AF	Yes	6 Meters	No
Yaesu FT-857D*	\$920	AF	Yes	6, 2 m; 70 cm	No
Yaesu FT-891	\$700	IF	Yes	6	No
Yaesu FT-991A‡*	\$1450	IF	Yes	6. 2 m: 70 cm	Yes

[†]Provides I/Q output for DSP with external PC and sound card.

Entry Loyal

^{**200} W output; requires one 40 A, or two 20 A power supplies.

Figure 1 — The Alinco DX-SR8T desktop HF transceiver. This is the lowest price 100 W HF transceiver, as this is written.

[‡]Single unit radio, others have separable control head.

^{*}FT-857D is 50 W output on 2 meters, 20 W on 70 cm; IC-7100 is 50 W output on 2 meters, 35 W on 70 cm; FT-991A is 50 W output on 2 m and 70 cm.

International Radio (www.inrad.net).

The IC-718 does not include an antenna tuner, but provision is made for one of two Icom external tuners — the AT-180 for coax fed antennas with an SWR of 3:1 or less (\$550), or the AH-4 for wire antennas (\$280, also usable for coax-fed antennas). Aftermarket tuners are also available from a number of manufacturers.

The IC-718 is generally easy to operate and includes all the basic controls and capabilities to get you on the air on HF. If you need to add features through available options, the price will go up considerably, bringing it more in line with, or even higher than, some of the other choices.

The Yaesu FT-450D, shown in **Figure 3**, is an updated version of the earlier FT-450 with more digital processing features. The FT-450D includes the 60 meter channels and 6 meters. It also provides for FM in addition to SSB, AM, CW and data operation. It is very much like its bigger and more expensive siblings in that it built around a common DSP architecture that provides multiple operating bandwidths to cover each mode. There are three fixed bandwidth choices each for CW, SSB, and AM. These are all built in without having to buy options. An internal antenna tuner is included with the base FT-450D.

The Yaesu FT-857D (**Figure 4**), is of the same generation as the IC-718, in that it uses analog IF filters and provides audio-based DSP. It offers the advantage of all-mode VHF and UHF operation in addition to HF.

The Kenwood TS-480SAT is priced near the top of this group. It is discussed in the following section, along with its somewhat higher priced 200 W sibling, the TS-480HX that trades the additional power for the internal tuner. Both TS-480s have a removable front panel and an Ethernet port, making it remote-control ready right out of the box.

The Yaesu FTDX1200 (**Figure 5**) straddles the mid-range and entry level categories. When this was written in early 2018, promotional pricing put it solidly in the entry level category. While the other radios in this group are quite compact, the FTDX1200 is more of a full-size transceiver. The larger size makes for easier to operate controls and a larger display, features that may be well worth some extra space, if it's available. This radio has a colorful display screen and shares many features of the FTDX3000 shown in the next section.

Figure 2 — The Icom IC-718 desktop HF transceiver.

Figure 3 — The Yaesu FT-450D desktop HF and 6 meter transceiver.

Figure 4 — The Yaesu FT-857D, an entry level transceiver with a mobile orientation and coverage up to 70 cm.

Portable and Mobile Transceivers

There are many choices in this category. These are 100 W (or more) HF transceivers that usually include one or more VHF/UHF bands. They have many of the features of larger radios, but they are compact and designed for the tight cockpit of modern vehicles, or for easy transportation to a portable location.

There is no reason these radios can't be operated from a home station as well. The usual trade-off is that they have smaller front panels with fewer and smaller controls. They often make up for the missing controls with more programmable menus that some operators may find cumbersome. Still, they may be perfect for a compact home radio station, and can be moved to a vehicle as well.

There are too many radios in this category to discuss separately, so we'll highlight some of the differences in **Table 1**. Note that all, except for the portable or field oriented FT-991A (**Figure 6**), have a removable front panel that is designed to be mounted in the front of a vehicle, while the body of the radio can be mounted in the rear or under a seat. All can be combined together in some way to

Figure 5 — The Yaesu FTDX1200 HF and 6 meter transceiver features a colorful screen and spectrum display.

Figure 6 — The Yaesu FT-991A HF, VHF and UHF transceiver offers a full color touch-display that features a full-time spectrum scope, as well as many other features.

Figure 7 — The Icom IC-7100 HF, 6 and 2 meter and 70 cm transceiver. This radio offers a convenient angled front panel for desktop or vehicle use and is the first with a touch screen, as well as knobs.

operate as a single unit for home or field use.

Yaesu's FT-991A is well into the midrange price category but with many advanced features, including dual roofing filters, a fulltime spectrum scope, and a touch-screen display. The Icom IC-7100 (Figure 7) has a separate front panel a bit different from others in that it is at an angle that can be easily viewed if used on a tabletop, or in some mobile arrangements. It also can be operated via touch screen, as well as via the usual controls. The Kenwood TS-480 (Figure 8) offers a choice of models with either an internal antenna tuner or a 200 W output transmitter, the only one in this price category to offer higher power. The Yaesu FT-891 (Figure 9) is an HF focused radio, supporting 160-6 meter operation with CW, AM, and SSB modes and DSP processing.

Some of these radios can operate into the VHF and UHF range. Not only do most operate FM there, but they can also operate SSB, CW and even AM, making them much more versatile than the usual VHF FM-only mobile setup. Some will even allow reception of wideband FM broadcast signals, but none will likely be confused with a high fidelity audio system.

Figure 8 — Kenwood TS-480HX, the only transceiver in this category with a 200 W transmitter. The TS-480SAT looks similar, but offers 100 W output and an internal antenna tuner.

Mid-Range Transceivers

What do you get if you dig a bit deeper into the checkbook? Generally, you get a somewhat larger radio with easier to grasp controls, more features — or more choices within a feature type, such as more operating bandwidths to choose from. All are relatively recent designs with IF DSP, allowing a wide range of operating bandwidths.

You also may get better receiver performance — perhaps one of the key elements that separate the radios at the higher price ranges. In this case we are talking about the ability to receive a weak signal within a kHz or two of a strong one — *close-in dynamic range*. The higher the number the better, and as noted there is quite a range. While this is only one of the many parameters evaluated in the ARRL Lab during the review process, some believe it is the key in a crowded operating environment such as contesting or DX chasing. When the band is crowded with very strong signals operating nearby, you can experience interference generated in your receiver caused by mixing products from those nearby signals or from reciprocal mixing noise from your frequency synthesizer. The higher the closein dynamic range, the less likely you are to experience internally generated interference to stations you are trying to hear.

There are three primary dynamic range limitations tested during ARRL Product Review testing: blocking gain compression dynamic range, intermodulation distortion dynamic range, and reciprocal mixing dynamic range. Since any of the three can be the limiting factor in dynamic range, the lowest is shown as "Min DR" in the tables for mid and higher-range transceivers, with the lowest dynamic range noted by BG for blocking, IM for intermodulation and RM for reciprocal mixing dynamic range.

It should be mentioned that, while data is shown for both traditional and software defined radio (SDR) receivers, their reactions to close in signals is somewhat different between the two platforms. SDR dynamic range can actually improve with multiple out of channel signals in the input. ARRL Lab testing procedures for SDR based receivers has been modified to make the results as comparable as possible.

Another consideration is transmitter linearity and dynamic range. Having an excellent receiver performance can be circumvented by having nearby transmitters with wide signals caused by various mechanisms in both CW and SSB modes. These factors are not reported here, but are shown in *QST* Product Reviews. For SSB, look for the level of intermodulation products and for CW the keying sidebands. The same frequency synthesizer

Table 2
Transceivers in the Mid-Range Category
All are 100 W transceivers.

^{††}Not yet tested in ARRL Lab.

Mid-Range Transceivers (continued)

phase noise that results in reciprocal mixing dynamic range on receive will result in wideband transmit signals as well. The best transceivers have good characteristics in both receive and transmit.

We have summarized some of the key features and parameters in Table 2. Elecraft offers two low powered portable transceivers, the KX2 (10 W) and KX3 (15 W), which are primarily designed for stand-alone field use, but if paired with the available Elecraft KXPA100 100 W HF and 6 meter linear amplifier become contenders for 100 W mid-range priced home station use. The KX2 offers HF operation only in a very compact package, although it can be used with transverters for VHF use, while the somewhat larger KX3 (Figure 10) adds 160 and 6 meter coverage and has room for an optional internal 2-meter transverter. The linear amplifier offers a wide range antenna tuner option. Both the KX2 and KX3 include display screens that are strikingly similar to that of their bigger brethren, the K3S.

The FlexRadio FLEX-6400 SDR offers excellent performance and can be used with software running on a PC or IOS device, as well as with the Maestro controller. The FLEX-6400M, in the Upper Mid-Range category, is the same radio built into a cabinet with a front panel and requiring no PC for operation. An antenna tuner is optional for both radios.

The Icom IC-7300 (**Figure 11**) uses full-SDR (direct-sampling) architecture in a conventional-looking HF transceiver package. The '7300 has a direct signal-frequency sampling front-end DSP processor that results in a simplified structure with excellent performance.

Some of the equipment needs a bit of additional explanation. Note that none of the radios in Table 2 include a fully-capable second HF receiver, but the TS-2000 (Figure 12) does have a second receiver mainly for VHF FM use — perhaps handy for some who wish to monitor their local repeater while operating HF. In the upper middle range some do have independent second receivers so that you can listen to signals on two frequencies — one in each ear, if you wish — handy while operating on split frequencies and a popular option with DX chasers.

The Kenwood TS-590SG (see **Figure 13**) offers a high performance down converting receive capability on some bands. The Yaesu FTDX3000 (**Figure 14**) is a lower priced, 100 W, single receiver version of "top drawer" FTDX5000.

Figure 12 — Kenwood TS-2000. This transceiver operates on MF, HF, VHF, UHF, as well as the 1.2 GHz band with an option (TS-2000X version), providing broad frequency coverage in a single package.

Figure 13 — The Kenwood TS-590SG offers a high performance receiver and many digital features.

Figure 14 — The Yaesu FTDX3000 offers high performance receiver, a 100 W transmitter and a colorful display screen.

Upper Mid-Range Transceivers

Transceivers in the upper mid-range group offer a number of choices between different desirable features. Key parameters are noted in **Table 3**. Some offer more or different features, while others make a push toward higher performance. At the top of the next bracket, manufacturers try to provide everything, while here you need to look carefully and decide what is most important.

The Elecraft K3S (**Figure 15**) provides excellent performance in this category and shows up in multiple categories because of its configuration flexibility. This radio is an upgrade of the original K3 including new synthesizer boards that deliver lower phase noise, a new internal pre-amp, replacing various external options, a new USB interface that replaces both the serial computer interface and the separate LINE IN and LINE OUT connections of the original. All modifications can be applied to the original K3, if desired.

Two distinct K3S versions are in this category including just the basic K3S 100 W components, making a top-notch single receiver set. At a somewhat higher price point we list the initial dual-receiver configuration. A fully loaded K3S transceiver makes it into the "top drawer" category. Any can be purchased as kit units with just mechanical assembly required at some cost savings, and upgrades can be added at any time.

To support remote-control operation, the K3S/0, a front-panel-only version, is available that can connect to a remotely located K3S via an Internet connection.

The Icom IC-7610 (**Figure 16**), a direct-sampling SDR building on the technology of the IC-7300, but adding a second independent receiver and other features.

The Icom IC-9100 (**Figure 17**) has the capability to serve as both an MF/HF transceiver and a multimode VHF/UHF radio with an option for the 1.2 GHz band.

Top Drawer Transceivers

Transceivers at the very top of the price range (Table 4) are available from a number of manufacturers. These transceivers span a considerable variation of prices, but from \$4000 and up it probably doesn't make too much sense to subdivide the list. Buying decisions are driven by subtle differences in features or the desire for optimum receiver performance, a key issue with many contest and DX-focused operators.

Among many families of transceivers, there is some flexibility here in terms of hardware. The previously discussed Elecraft K3S epitomizes flexibility through its extensive options list, as well as top-shelf receiver performance. It is definitely a radio that can grow with the operator's needs!

The Hilberling PT-8000A (Figure 18) provides professional-quality coverage of HF and VHF (6, 4, and 2 meters — with 4 meter transmit offered only in the European version). The PT-8000A offers superb analog receiver performance through the use of cascaded 12-pole crystal filters, followed by optional additional IF DSP selectivity and processing. At Icom's top end, the IC-7851 (Figure 19) features two high-performance receivers, a low-noise synthesizer, flexible panadapter, and a host of other high-end features. The IC-7700 is basically an IC-7800 (the predecessor to the '7851) without a second receiver - not something that is needed for every application.

Figure 18 — The Hilberling PT-8000A offers a top quality HF and VHF transceiver from Germany.

Figure 19 — The Icom IC-7851 provides excellent performance and an extra flexible display system.

^{†10} W on 2 meters.

^{‡100} W on VHF.

^{††}Not yet tested in ARRL Lab.

An SDR transceiver from FlexRadio is in this category. The FLEX-6700 (**Figure 20**) offers advanced features including eight simultaneous receive and display channels. The FLEX-6600 is similar, but offers four independent receive channels. The FLEX-6600M places the FLEX-6600 in a cabinet with front panel display and controls, and does not require a PC for operation.

The ANAN 8000DLE (**Figure 21**) from Apache Labs is another high-end SDR that offers multiple high-performance receivers and a 200 W transmitter with a Pure Signal function that reduces transmitted IMD products.

The Yaesu FTDX5000MP (**Figure 22**) offers exceptional receiver close-in intermodulation dynamic range, as measured in the ARRL Lab. It includes a more precise master oscillator and a 300 Hz roofing filter as well as a 200 W PEP transmitter. Kenwood's top drawer TS-990S (**Figure 23**) offers two independent high performance receivers, a spectrum scope, and many other features.

Figure 20 — The FlexRadio Systems FLEX-6700 is a powerful SDR that can run up to 8 receivers simultaneously and has exceptional phase noise and dynamic range characteristics.

Figure 21 — The ANAN 8000DLE SDR from Apache Labs includes multiple highperformance receivers and a 200 W transmitter with Pure Signal capability.

Figure 22 — The Yaesu FTDX5000MP is a top-performing 200 W transceiver with a 300 Hz roofing filter. The unit on top is the optional SM-5000 station monitor. The similar FTDX5000 is shown.

Figure 23 — The Kenwood TS-990S HF and 6 meter transceiver offers dual high performance receivers and a spectrum scope.

Software Defined Radios

We described some HF transceiver choices as "software-defined radios" or SDR. It may be worth a short digression to discuss this topic in the context of available equipment. Software-defined radio architecture and design is covered in more detail in the **DSP** and **SDR Fundamentals** and the **Receiving** chapters.

In the amateur environment, we are particularly interested in radios that can be changed through software by the end user or operator to meet their needs or to take advantages of newly developed capabilities.

The ideal SDR would thus have a minimum of physical constraints. On the receive side, the antenna would be connected to an analog-to-digital converter that would sample the entire radio spectrum. The digitized signal would enter a processor that could be programmed to analyze and decode any form of modulation or encoding and present the result as sights and sounds on the output side of the processor.

On the transmit side, the processor would accept any form of information content, convert to digital if needed, process it into a waveform for transmission and send out a complex waveform conveying the information as an RF signal on the appropriate frequency or frequencies, at the desired power level to transmit from the antenna.

While in the past, our utopian SDR was much easier to imagine than to construct, Icom and FlexRadio have introduced transceivers that are implementations of this principle in a package that looks and feels like a typical transceiver. Other manufacturers offer "blank front panel" radios that also make use of SDR technology, but still require a separate PC for operation, control, and display functions. As a practical matter, a typical PC has some constraints that don't allow us to do everything we want within the PC. Manufacturers have thus moved the high-speed analog-to-digital conversion processing into their radios, leaving the more routine processing for the connected PC. While most modern transceivers can operate under the control of a PC, if desired, the more traditional looking transceivers include all the processing needed for their own functions and display.

The key to amateur SDR operation with a PC remains the analog-to-digital conversion process. This is the point at which the analog RF signals are digitized for processing. Early and more basic SDRs made use of a computer's sound card, or sometimes an external interface device, to perform this function. The typical computer sound card is usually

the limiting point in terms of performance, as described below. More advanced SDRs, as described above, have the processing functionality built in and are thus able to take advantage of higher performance processing engines that can sample faster, allowing the direct processing of higher frequencies with each generation. They also can provide a higher dynamic range than typical sound cards.

The software will determine the type of processing and the nature of the signals we can deal with. It can also take the results of processing and convert them into an analog signal. This sounds like just what we are looking for to make an SDR — and it is. Such an SDR in receive mode would consist of the blocks in **Figure 24**. We do have a few significant limitations:

- For most sound cards the sampling rate is 192 kHz or less, limiting the received analog signal to a frequency of 96 kHz. Some kinds of dual channel processing allow a response as high as the sampling rate. (Sampling rate limitations, also referred to as Nyquist rate, require sampling the incoming signal at twice the highest frequency in the sampled signal.)
- Most sound cards do not have the sensitivity required in a radio receiver and on the transmit side can only output 100 mW or less.

It is for these reasons that the newest high performance SDR transceivers no longer depend on the PC for the A/D conversion process, instead using newly available high-speed processors within the SDR platform itself. While the PC's control screen may seem similar, the PC is now primarily used for the control and display functions with the "heavy lifting" happening in dedicated circuitry within the SDR.

The SDR designer, as with all designers, is faced with a trade off. The equipment external

to the PC required to make it do what we want may also limit the choices we can make by software change in the PC. The more hardware features we build in, the fewer choices we may have. In addition to PC software, there is often firmware, hard wired instructions in the box outside the PC. This has resulted in two general approaches in SDR.

THE "BLANK FRONT PANEL" ARCHITECTURE

Radios marketed as SDRs tend to be of this type. The best known are several generations of transceivers from FlexRadio Systems, which started with the SDR-1000, reviewed in *QST* in 2005. The current generation is a family of SDR systems called the FlexRadio Signature Series. One radio from that offering, the FLEX-6700 appears in Table 4. The front panel has no controls and all control functions are implemented by soft buttons on the software's computer screen. (Figure 25 shows SmartSDR for Windows, used with the FlexRadio 6000 series radios.) FlexRadio also offers an optional FlexControl USB tuning knob that connects to the computer and the Maestro, a feature-laden control head that avoids the need for a connected PC.

There are a number of similarly configured radios usable with open source *PowerSDR* software freely available under the GNU Public License. These include the SDR transceivers from Apache Labs, and the modular High Performance SDR system available through Tucson Amateur Packet Radio (TAPR). There are also a number of very low cost SDRs available from various vendors. (Source code for software called "open source" can be viewed and modified. Thus, not only can you upgrade the radio, but also change functionality to make the radio do what you want.)

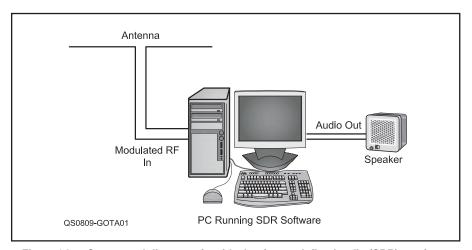

Figure 24 — Conceptual diagram of an ideal software-defined radio (SDR) receiver.

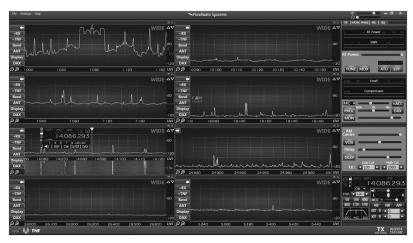

Figure 25 — One version of the main operating screen of *SmartSDR for Windows* operating software for the Flex 6000 series transceivers. In this case a FLEX-6700 has eight receivers and panadapters going simultaneously.

THE "LOOKS LIKE A RADIO" APPROACH

Many current radios are actually built as SDRs. Some, such as the Elecraft K3S, and Yaesu FTDX3000, for example, are provided with a mechanism to allow an easy end-user upgrade to new firmware revisions. The Icom IC-7300 took this to a new level with analog-to-digital conversion at the signal frequency (direct-sampling), and now has been joined by the more advanced IC-7610. These radios look like most any other pre-SDR radio in that they have front panels with knobs and dials and displays. Unless you looked at all the revisions to the operating instructions you wouldn't know that they were field-reconfigurable.

Another distinction between the groups is that most of the firmware for the radios in this group is proprietary with revisions available only from the manufacturer, at least as of this writing. That isn't to say that a solid programmer couldn't and perhaps hasn't developed

custom software for one of these radios, but it hasn't happened often.

While all radios in this group are designed primarily to operate without an external computer, they all can be computer controlled using aftermarket software, available from multiple developers. While this software can make them feel a bit like the radios in the other group, the operating parameter ranges are all set by the radio's internal operating firmware.

DIFFERENCES IN PERFORMANCE

The blank front panel architecture radios generally have the most flexibility in operation, since they are not constrained by the physical buttons and knobs on the front panel. The more traditional-looking versions with physical controls and displays may take advantage of those hardware constraints to gain improved performance at the expense of operating flexibility, but a look at the specs will indicate that it isn't always the

case. Some blank front panel SDRs offer top shelf performance.

There will always be some who prefer the more traditional radios and are happy to have it configured and to let it stay the way they like it. Others, especially those who enjoy computers as well as radios, will prefer a transceiver that might get better with the next generation of computers, sound cards, or software. What's really nice is that we can go whichever direction we choose!

Making a Selection

You know the facts — how can you choose? Looking at tables and product reviews (all *QST* Product Reviews since 1980 are provided to ARRL members online at **www.arrl.org/product-review**) provides a great start, but just as with finding the perfect life partner, the numbers don't tell it all. With radios there's also an element of love at first sight, tempered by the way the radio feels to you as you operate it — ergonomics.

Each manufacturer has a different philosophy for structuring the controls and menus, and you may find a great preference for one person-to-machine interface over another. The *QST* Product Reviews attempt to capture some of the subjective impressions, at least as seen through the eyes of the reviewer.

If you have an opportunity, try out the radios you are thinking of buying. If you are in a local club, find out who uses radios that you are considering and seek an invitation to come over and try them out. Most hams love to show off their stations. Perhaps you have a nearby dealer who has some demo setups, or you can find some at a larger hamfest, or at Field Day. If you're in the northeast, drop by ARRL Headquarters and be a guest operator at W1AW — we have many radios available to try. Nothing beats a test drive!

Extending HF Transceiver Coverage to Include VHF/UHF

Transceivers discussed so far include a wide range of features and operational capability. While some transceivers offer capability into the microwave region, most amateurs start with a transceiver that operates over the MF to HF frequency range, often extending into VHF at 6 meters. It is also true that most amateurs have at least a passing acquaintance with the higher VHF bands, perhaps 2 meter or 70 cm FM communications, through local repeaters.

At some point, many amateurs have heard enough about satellite communication or exotic beyond-line-of-sight propagation such as troposcatter, sporadic-E layer communication or moonbounce to want to try these activities. They take place using SSB, CW and narrow bandwidth digital modes, so a VHF/UHF FM transceiver won't do, although the FM satellites are almost as easy to use as the local repeater.

As noted previously, several HF transceivers also cover through the VHF bands and some into UHF at 70 cm. Among the entry level and portable/mobile radios, the Icom IC-7100, Yaesu FT- 857D and FT-991A all include VHF operation on 6 and 2 meters and 70 cm, supporting SSB, CW, AM, and FM modes on each band.

Two current full size HF transceivers extend operation well into the VHF and UHF regions as well. The Kenwood TS-2000 and Icom IC-9100 not only offer all modes of operation from 160 meters to 70 cm, but each also offers an internal option for the 23 cm (1240 to 1300 MHz) microwave amateur band. Each can support FM repeater operation as well as the full duplex modes needed for operation through satellites. Note that no current HF transceivers include transmission capability on the 1.25 meter band.

Using an HF Transceiver at VHF/UHF

If you have the HF transceiver you want and would like to try the higher VHF and UHF bands, a viable option is a VHF or UHF transverter. A transverter essentially adds an additional conversion stage, along with preand post-amplification, to translate receive and transmit frequencies to a new range.

At VHF, UHF and microwave frequencies, transverters that interact with factory-made transceivers in the HF or VHF range are common and are often home-built. These units convert the transceiver transmit signal up to a higher frequency and convert the VHF/UHF receive frequency down to the trans-

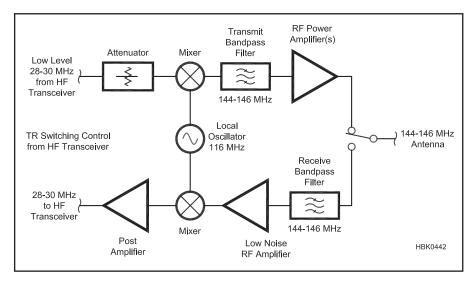

Figure 26 — Block diagram of a basic 2-meter to 10-meter transverter.

ceiver receive frequency. The configuration of a typical 2 meter transverter is shown in **Figure 26**.

For microwave frequencies, it's common for transverters to have a 144-MHz IF for connection to a multimode 2 meter transceiver. Use of a higher IF frequency range makes image filtering easier. Sometimes transverters use two stages of conversion — microwave to 2 meters, and then 2 meters to 10 meters, for use with an HF transceiver.

The resulting performance and signal quality at the higher frequencies are enhanced by the frequency stability, bandwidth filters and signal processing capabilities of the transceiver. A transverter makes stable SSB and CW operation feasible on bands from 144 through 10 GHz and higher.

TRANSVERTER DESIGN

The methods of individual circuit design for a transverter are not much different than methods that have already been described. The most informative approach would be to carefully study an actual project description. The interface between the transceiver and transverter requires some careful planning. For example, the transceiver power output must be compatible with the transverter's input requirements. This may require an attenuator (or an amplifier) or some modifications to a particular transverter or transceiver. There is no standard level among transceiver and transverter brands, so check to see that your HF transceiver has a low-level transmitter output. Also important: a dedicated receiver input for transverter use, as well as some provision for TR switching.

The Elecraft K3S is an example of an HF transceiver with well thought-out transverter provisions. It has dedicated, separate transverter input and output ports (an optional board required in the earlier K3). In addition, the band switch directly supports transverters just as if they were bands within the transceiver. The frequency display shows the VHF or UHF frequency directly for up to nine transverter bands. The appropriate IF frequency is set up for each band, typically 10 or 6 meters, but any others also can be

Table 5
Key Performance and Operational Specifications of Transverters Measured in the ARRL Lab

Model	Band	Receive Gain (dB)	Noise Figure (dB)	Image Rejection (dB)	Output Power (W)

^{*}Formerly listed, and in QST Product Reviews as Down East Microwave.

^{**}Internal option for K3 or K3S transceiver.

used. An offset is applied to the frequency calibration to compensate for any error in the local oscillator frequency of the selected transverter and a control signal is sent to select the transverter depending on band selected.

The receive converter gain must not be so large that the transceiver front-end is over-driven, causing intermodulation and blocking. On the other hand, the transverter gain must be high enough and its noise figure low enough so that the overall system noise figure is within a dB or less of the transverter's own noise figure.

AVAILABLE TRANSVERTERS

If building a transverter from scratch is not for you, a number of manufacturers produce assembled or kit transverters for many VHF through microwave bands. Transverters that have been reviewed in *QST* include the following, with key ARRL Lab results summarized in **Table 5**:

The Down East Microwave VHF transverters had been made for them by Q5 Signal (www.q5signal.com), which will now sell and support them directly. Down East will continue to provide transverters from 900 MHz and up, as well as other products. The ARRL reviewed their L144-28HP 2 meter transverter (Figure 27) and a similar transverter for 222 MHz, the L222-28.

Elecraft makes transverter kits from 6 to 1.25 meters. The ARRL reviewed their XV144 2 meter transverter kit (**Figure 28**). They also offer a 2 meter transverter, the K144XV, that is designed to fit within the K3 or K3S (also reviewed in *QST*). With the addition of the K144XV, either K3 model covers 160 through 2 meters from a single compact box. The portable and trail oriented KX3 has provision for an internal 2 meter transverter, as well.

Kuhne Electronics (DB6NT) makes transverters for many VHF, UHF, and microwave bands. The ARRL reviewed their MKU 10 GHz transverter in *OST*.

A number of online-only vendors are beginning to offer VHF, UHF, and microwave transverters for sale. Check e-commerce sites

Figure 27 — The Q5 Signal (formerly Down East Microwave) L144-28HP transverter turns an HF transceiver into a 2 meter all-mode transceiver with sensitive receiver and 60 W output.

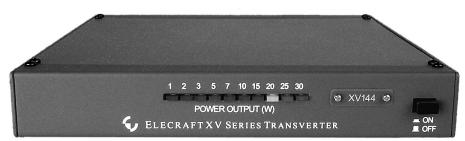

Figure 28 — Elecraft's XV144 2-meter transverter kit integrates seamlessly with their K2, K3 and K3S HF transceivers. It works with other radios too, as long as they have appropriate input and output connections.

for availability. VHF+ clubs and user groups may have more information about quality and availability of these units which are often made by small companies in batches.

Transceivers for Use with **Transverters**

While almost any of the HF transceivers we have discussed can be made to operate with a transverter, some make for an easier fit than others. **Table 6** shows transceivers

in the low power (QRP) category that we excluded from our tables as discussed earlier. While they provide lower power on HF than our threshold, that is not a disadvantage for transverter use.

The key requirements for selecting a transceiver for transverter use are that they provide:

- Separate transmit and receive signal paths (not needed for all transverters).
- Control of RF output power down to low levels needed by most transverters. Having a

Table 6

^{††3} W on 2 meters.

^{†††}Not yet tested in ARRL Lab.

separate low power transverter port avoids the chance that you will accidently put 100 W on 20 meters, for example, into your transverter.

• Transmit-receive switching control available to switch the transceiver and transverter in proper sequence. While on many radios the TR control output designed for linear amplifier switching can be pressed into service, a dedicated port for transverters is a plus.

In addition, nice but not absolutely necessary features are:

- A frequency display that indicates the transverter operating frequency directly rather than the transceiver's tunable IF frequency.
- The ability to input a frequency calibration offset to compensate for any error in the transverter's heterodyne oscillator frequency.

While a number of the radios discussed earlier can meet these requirements, the QRP radios described here offer most needed features at relatively low cost.

The Elecraft K3S series radios are particu-

larly well suited for transverter use. The K3S includes the functionality of the formerly optional KXV3 transverter interface board that provides the desired low level transmit signal and needed ports for transverter interface. Table 6 shows the key parameters for a K3S optioned in the minimal configuration for transverter use. As provisioned, it can support automatically switching in up to nine transverters, each with its own frequency display (up to 25 GHz) and frequency offset.

Of course other options can be added if it is desired to also use the same transceiver as a 100 W HF transceiver as well. Some will also be helpful for transverter operation. For example, the internal 2 meter transverter option is a natural if microwave transverters are to be employed. A second receiver can be helpful to monitor an HF coordination frequency while attempting moonbounce or other sophisticated communication modes. A big advantage of the K3S is that it all is

contained in a single compact box. Even more compact is the KX3, a very portable DSP transceiver that has provision for 2 meters in the box. The front panel appears identical to its bigger brother, the K3S, but the total package is much smaller — think raincoat pocket. The KX2 is an even smaller HF-only 10 W transceiver. Both the KX2 and KX3 include provision for nine transverter bands, but they require connection via a single transmit-receive port, and the output must be reduced to match the transverter input. The KX3, with its internal 6-meter and optional 2-meter coverage may have the edge for those who use microwave transverters with a a VHF IF frequency.

The popular Yaesu FT-817, a micro-size 5 W SSB, CW and FM transceiver that covered the HF, VHF and UHF bands, has been replaced by a similar transceiver with slightly more power, the FT-818.

Radio Mathematics

This supplement is a collection of tutorial information on a variety of mathematics used in Amateur Radio. Many of the fundamental relationships in electronics and radio are best expressed in the language of math. This chapter will expand in subsequent editions as it becomes clearer what information will be useful to readers. Material in this chapter has been collected from many sources, authors, and instructors over the years — the ARRL appreciates their contributions.

1 The Metric System

1.1 Metric Prefixes —the Language of Radio

The units of measurement employed in radio use the *metric system* of prefixes. The metric system is used because the numbers involved cover such a wide range of values. **Table 1** shows metric prefixes, symbols, and their meaning. The prefixes expand or shrink the units, multiplying them by the factor shown in the table. For example, a kilo-meter (km) is one thousand meters and a milli-meter (mm) is one-thousandth of a meter.

The most common prefixes you'll encounter in radio are pico (p), nano (n), micro (μ), milli (m), centi (c), kilo (k), mega (M) and giga (G). It is important to use the proper case for the prefix letter. For example, M means one million and m means one-thousandth. Using the wrong case would make a big difference!

The metric system uses a basic unit for each different type of measurement. For example, the basic unit of length is the *meter* (or metre). The basic unit of volume is the *liter* (or litre). The unit for mass (or quantity of matter) is the *gram*. The *newton* is the metric unit of force, or weight, but we often use the gram to indicate how "heavy" something is by assuming a standard value of gravity.

Table 1 summarizes the most-used *metric prefixes*. The metric system expresses larger or smaller quantities by multiplying or dividing the basic unit by factors of 10 (10, 100, 1000, 10,000 and so on). These multiples result in a standard set of prefixes, which can be used with all the basic units. Even if you come across some terms you are unfamiliar with, you will be able to recognize the prefixes.

We can write these prefixes as powers of 10, as shown in Table 1. The power of 10 (called the *exponent*) shows how many times you must multiply (or divide) the basic unit by 10. For example, we can see from the table that kilo means 10^3 . Let's use the meter as an example. If you multiply a meter by 10 three times, you will have a kilometer. $(1 \text{ m} \times 10^3 = 1 \text{ meter} \times 10 \times 10 \times 10 = 1000 \text{ meters}, \text{ or } 1 \text{ kilometer.})$

If you multiply 1 meter by 10 six times, you have a megameter. (1 meter $\times 10^6 = 1$ m $\times 10 \times 10 \times 10 \times 10 \times 10 \times 10 = 1,000,000$ meters or 1 megameter.)

Notice that the exponent for some of the prefixes is a negative number. This indicates that you must divide the basic unit by 10 that number of times. If you divide a meter by 10, you will have a decimeter. (1 meter $\times 10^{-1} = 1 \text{ m} \div 10 = 0.1 \text{ meter}$, or 1 decimeter.) When we write 10^{-6} , it means you must divide by 10 six

Table 1
International System of Units (SI) — Metric Units

Prefix	Symbol	Multiplication Factor
Tera	T	$10^{12} = 1,000,000,000,000$
Giga	G	$10^9 = 1,000,000,000$
Mega	M	$10^6 = 1,000,000$
Kilo	k	$10^3 = 1000$
Hecto	h	$10^2 = 100$
Deca	da	$10^1 = 10$
Deci	d	$10^{-1} = 0.1$
Centi	С	$10^{-2} = 0.01$
Milli	m	$10^{-3} = 0.001$
Micro	μ	$10^{-6} = 0.000001$
Nano	n	$10^{-9} = 0.000000001$
Pico	p	$10^{-12} = 0.000000000001$

1 M = 1000 k; 1 m=1000 μ = 1,000,000 n; 1 μ =1000 n=1,000,000 p

times. (1 meter $\times 10^{-6} = 1 \text{ m} \div 10 \div 10 \div 10 \div 10 \div 10 \div 10 = 0.000001 \text{ meter, or 1 micrometer.)}$

We can easily write very large or very small numbers with this system. We can use the metric prefixes with the basic units, or we can use powers of 10. Many of the quantities used in basic electronics are either very large or very small numbers, so we use these prefixes quite a bit. You should be sure you are familiar at least with the following prefixes and their associated powers of 10: giga (10^9) , mega (10^6) , kilo (10^3) , centi (10^{-2}) , milli (10^{-3}) , micro (10^{-6}) and pico (10^{-12}) .

Let's try an example. For this example, we'll use a term that you will run into quite often in the Handbook: hertz (abbreviated Hz, a unit that refers to the frequency of a radio wave). We have a receiver dial calibrated in kilohertz (kHz), and it shows a signal at a frequency of 28,450 kHz. Where would a dial calibrated in hertz show the signal? From Table 1 we see that kilo means times 1000. The basic unit of frequency is the hertz. That means that our signal is at $28,450 \, \text{kHz} \times 1,000 = 28,450,000 \, \text{hertz}$. There are 1000 hertz in 1 kilohertz, so $28,450,000 \, \text{divided}$ by 1000 gives us $28,450 \, \text{kHz}$.

If we have a current of 3000 milliamperes, how many amperes is this? From Table 1 we see that milli means multiply by 0.001 or divide by 1000. Dividing 3000 milliamperes by 1000 gives us 3 amperes. The metric prefixes make it easy to use numbers that are a convenient size simply by changing the units. It is certainly easier to work with a measurement given as 3 amperes than as 3000 milliamperes!

Notice that it doesn't matter what the units are or what they represent. Meters, hertz, amperes, volts, farads or watts make no

difference in how we use the prefixes. Each prefix represents a certain multiplication factor, and that value never changes.

1.2 Converting Between Types of Units

Converting between different types of units requires a *conversion factor*. The conversion factor is a value representing how many units of Type A are equivalent to a single unit of Type B, generally given as (amount of units of Type B) per (unit of Type A).

For example, the conversion factors between pounds (Type A) and kilograms (Type B) are 0.455 kg/lb and 2.2 lb/kg.

To decide which to use in converting units of Type A to Type B, select the factor with the Type B units in the numerator of the conversion factor. Multiply the amount of Type A units by the conversion factor.

For example, to convert 3 lb (Type A) to kg (Type B):

- 1. Select the conversion factor with Type B units (kg) in the numerator, 0.455 kg/lb
 - 2. Multiply the amount of Type A units by the conversion factor: $3 \text{ lb} \times 0.455 \text{ lb/kg} = 1.37 \text{ kg}$

Similarly, to convert 3 kg (Type A) to lb (Type B):

- 1. Select the conversion factor with Type B units (lb) in the numerator, 2.2 lb/kg
 - 2. Multiply $3 \text{ kg} \times 2.2 \text{ lb/kg} = 6.6 \text{ lb}$

Note that these conversion factors are reciprocals. You can change one conversion factor into the other by calculating 1 divided by the conversion factor. Exchange the numerator and denominator at the same time:

$$1/(0.455 \text{ kg/lb}) = 2.2 \text{ lb/kg}$$
 and $1/(2.2 \text{ lb/kg}) = 0.455 \text{ kg/lb}$

You can also convert Type B units into Type A by dividing the amount of Type B units by the conversion factor from Type A to Type B:

$$10 \text{ kg} / 0.455 \text{ kg/lb} = 22 \text{ lb}$$

Note that not all conversions are simple multiplications or divisions. Additional offsets or factors may be required. For example, to convert degrees Fahrenheit to degrees Celsius, the formula is:

$$Deg C = 5/9 \times (Deg F - 32)$$

The *Handbook's* **Component Data and References** chapter includes a table of conversion factors for US Customary Units and between US Customary Units and Metric Units. Online calculators abound. Google (**www.google.com**) provides a unit converter accessible by entering "convert [abbreviation or name for Type A units] to [abbreviation or name for Type B units]" into an Internet search window.

2 Numbers and Notation

2.1 Accuracy, Resolution, and Precision

The terms accuracy, precision, and resolution are often confused and used interchangeably, when they have very different meanings. When dealing with measurements and test instruments, it's important to keep them straight.

- Accuracy is the ability of an instrument to make a measurement that reflects the actual value of the parameter being measured. An instrument's accuracy is usually specified in percent or decibels (see below) referenced to some known standard.
- *Precision* refers to the smallest division of measurement that an instrument can make repeatedly. For example, a metric ruler divided into mm is more precise than one divided into cm.
- Resolution is the ability of an instrument to distinguish between two different quantities. If the smallest difference a meter can distinguish between two currents is 0.1 mA, that is the meter's resolution.

It is important to note that the three qualities are not necessarily mutually guaranteed. That is, a precise meter may not be accurate, or the resolution of an accurate meter may not be very high, or the precision of a meter may be greater than its resolution. It is important to understand the difference between the three.

2.2 Accuracy and Significant Figures

The calculations you will find throughout the *Handbook* follow the rules for accuracy of calculations. Accuracy is represented by the number of *significant digits* in a number. That is, the number of digits that carry numeric value information beyond order of magnitude. For example, the numbers 0.123, 1.23, 12.3, 123, and 1,230 all have three significant digits.

The result of a calculation can only be as accurate as its *least* accurate measurement or known value. This is important because it is rare for measurements to be more accurate than a few percent. This limits the number of useful significant digits to two or three. Here's another example; what is the current through a $12-\Omega$ resistor if $4.6\,\mathrm{V}$ is applied? Ohm's Law says I in amperes =4.6/12=0.3833333... but because our most accurate numeric information only has two significant digits (12 and 4.6), strictly applying the significant digits calculation rule limits our answer to 0.38. One extra digit is often included, 0.383 in this case, to act as a guide in rounding off the answer.

Quite often this occurs because a calculator is used, and the result of a calculation fills the numeric window. Just because the calculator shows 9 digits after the decimal point does not mean that is a more correct or even useful answer.

2.3 Scientific and Engineering Notation

Modern electronics often uses numbers that are either quite large or very close to zero. At either extreme, it is difficult to write the numbers because of all the zeros. For example, the speed of light at which radio waves travel in a vacuum is 300,000,000 m/s. Similarly, a 22 pF capacitor would be written as 0.000000000022 F. These are values written in *decimal form* where all of the significant digits are

present, including the place-holding zeros. This is a very inconvenient format for calculation.

Instead, most large and small values in electronics are written in a special type of *exponential notation* called *scientific notation*. Numbers written this way consist of a value multiplied by 10 raised to an integer power. A number written in normalized scientific notation looks like this:

 $\pm D.DD \times 10^{\pm EE}$

where D.DD is a decimal value between 1 and 10, such as 3.14 or 7.07. EE is an exponent of 10, generally between 0 and 99. The following are a few ways of writing the same number in scientific notation several ways:

 $567 \text{ kHz} = 5.67 \times 10^5 \text{ Hz}$ = $5.67 \times 10^2 \text{ kHz}$ = $5.67 \times 10^{-1} \text{ MHz}$ = $5.67 \times 10^{-4} \text{ GHz}$

Because electronic units of measurements generally follow metric prefixes such as μ F or MHz, it is most convenient to give values in these units while still using the general form of scientific notation. This is called *engineering notation*. For engineering notation, the exponent must be a multiple of 3, such as -6, -3, 3, 6, or 12. These correspond to the various metric prefixes listed earlier. This means the number is written:

 $\pm DDD.DD \times 10^{\pm EE}$ (units)

Because standard units are used, engineering notation is easier to work with. For example, the most convenient units can be used throughout a calculation:

 $\begin{array}{ll} 2.47 \ V &= 2.47 \times 10^{0} \ V \\ &= 2.47 \times 10^{3} \ mV \\ &= 2.47 \times 10^{6} \ \mu V \end{array}$

Similarly, the value of a 151 $k\Omega$ resistor could be written several ways:

151 kΩ = 151×10^{3} Ω = 151×10^{0} kΩ = 151×10^{-3} MΩ

Your calculator may have the ability to perform calculations in exponential, scientific, and engineering notation. It is worth figuring out how to use these formats if you plan on doing any electronic value calculations.

2.4 Rate of Change

The symbol Δ represents "change in" a following variable, so that Δ I represents "change in current" and Δ t "change in time". A rate of change per unit of time is often expressed in this manner. When the amount of time over which the change is measured becomes very small, the letter d replaces Δ in both the numerator and denominator to indicate infinitesimal changes. This notation is often used in functions that describe the behavior of electric circuits.

3 Decibels

Decibels (abbreviated dB) are just a way of expressing ratios, usually power ratios. If you are looking at the gain of an amplifier stage, the pattern of an antenna, or the loss of a transmission line you are generally interested in the ratio of output power to input power. In antenna work, you are often concerned with the ratio of the power coming from the front of a beam antenna to that coming from the back. These are some of the places where you will find the results expressed in dB.

Decibels are a logarithmic function. An important feature of logarithms is that you can perform multiplication by adding logarithmic quantities instead of multiplying them. Similarly, you can divide numbers by subtracting in the same manner. This becomes a benefit if you are dealing with multiple stages of amplification and attenuation — as you often are doing in radio systems. In a radio receiver instead of having to multiply and divide the gains or losses of each stage to keep track of the signal processing — often with signal levels with many zeros to the right of the decimal point — you can just add up all the dB and determine the total gain in the system.

The *deci* in decibels refers to a factor of 1/10, as in *deciliters* for ½0 of a liter, while the *bel* relates to the idea of a logarithmic ratio, originally used to define sound power. The bel was named after Alexander Graham Bell, the inventor of the telephone.

3.1 Calculating Decibels from Ratios

To convert a power ratio into decibels:

- 1. Find the base 10 logarithm of the power ratio.
- 2. Multiply by 10.

 $dB = 10 \log_{10} (power ratio)$

The same decibels can be used to represent voltage or current ratios, rather than power ratios. Since power goes up with the square of the voltage or current, assuming the same impedance, the voltage or current ratios must be squared as well. With logarithms, ratios are squared merely by multiplying by two. Thus everything works the same way as for power calculations, except we multiply (or divide) by 20 instead of 10:

 $dB = 20 \log_{10} (voltage or current ratio)$

If you are comparing a measured power or voltage $(P_M \text{ or } V_M)$ to some reference power $(P_{REF} \text{ or } V_{REF})$ the formulas are:

$$dB = 10 \log_{10} \left(\frac{P_M}{P_{REF}} \right) = 20 \log_{10} \left(\frac{V_M}{V_{REF}} \right)$$

Positive values of dB mean the ratio is greater than 1 and negative values of dB indicate a ratio of less than 1. Ratios greater than 1 can be referred to as *gain*, while ratios less than 1 can be called a *loss* or *attenuation*. Note that loss and attenuation are often given as positive values of dB (for example, "a loss of 10 dB" or "a 6 dB attenuator") with the understanding that the ratio is less than one and the calculated value of change in dB will be negative.

For example, if an amplifier turns a 5-watt signal into a 25-watt signal, that's a gain of:

$$dB = 10 \log_{10} \left(\frac{25}{5}\right) = 10 \log_{10} (5) = 10 \times (0.7) = 7 dB$$

On the other hand, if by adjusting a receiver's volume control the audio output signal voltage is reduced from 2 volts to 0.1 volt, that's a change of:

Decibels In Your Head

Increasing power by a factor of 2 is a 3-dB increase and a factor of 4 increase is a 6-dB increase. When you increase power by 10 times, you have an increase of 10 dB. You can also use these same values for decreasing power. Cut power in half for a 3-dB loss of power. Reduce power to $\frac{1}{4}$ the original amount for a 6-dB loss. Reducing power to $\frac{1}{6}$ 0 of the original amount is a 10-dB loss. Power-loss values are written as negative values: -3, -6 or -10 dB. The following tables show these common decibel values and ratios.

You can also derive all the dB equivalents of integer ratios by adding or subtracting dB values. For example, to calculate a power ratio of 10/4 (2.5) in dB, subtract the dB equivalents for 10 and 4: 10-6=4 dB. Similarly for a ratio of 10/2 (5), 10-3=7 dB. The ratio of 5/4 (1.25) is 7-6=1 dB and so forth. The same trick can be used with the voltage ratios.

$$dB = 20 \log_{10} \left(\frac{0.1}{2} \right) = 20 \log_{10} (0.05) = 20 \times (-1.3) = -26 dB$$

A very useful value to remember is that any time you double the power (or cut it in half), there is a 3 dB change. A two-times increase (or decrease) in power results in a gain (or loss) of:

$$dB = 10 \log_{10} \left(\frac{2}{1}\right) = 10 \log_{10} (2) = 10 \times (0.3) = 3 dB$$

See the sidebar "Decibels In Your Head" for a guide to easy values of dB you can remember and apply quickly without having to use a calculator.

3.2 Calculating Ratios and Percentages from Decibels

To convert decibels to a power ratio, we do the opposite:

- 1. Divide by 10 (or 20 if converting to a voltage or current ratio)
- 2. Find the base 10 antilog of the result.

Note that the base 10 antilog of a number is just 10 raised to the power of the number. This is also something you probably don't do in your head, so let's see how you can easily perform the computations.

Understanding a few characteristics of logs will help avoid problems interpreting results. Note that a gain of 0 dB, means that there is no change to the signal — not that the signal has vanished! The other important fact is that a power ratio of less than one (a loss rather than a gain) results in a negative number in decibels.

power ratio =
$$\log^{-1} \left(\frac{dB}{10} \right)$$
 and

voltage ratio =
$$\log^{-1} \left(\frac{dB}{20} \right)$$

Note that the antilog is the same as the inverse log (written as \log_{10}^{-1} or just \log^{-1}). Most calculators use the inverse log notation. On scientific calculators the inverse log key may be labeled LOG⁻¹, ALOG, or $10^{\rm X}$, which means "raise 10 to the power of this value." Some calculators require a two-button sequence such as INV then LOG

Example 1: A power ratio of 9 dB = $\log^{-1} (9 / 10) = \log^{-1} (0.9) = 8$ **Example 2:** A voltage ratio of 32 dB = $\log^{-1} (32 / 20) = \log^{-1} (1.6)$ = 40 Since percentage is already a ratio, you can work directly in percentages when converting to dB:

$$dB = 10 log \left(\frac{Percentage\ Power}{100\%} \right)$$

$$dB = 20 log \left(\frac{Percentage\ Voltage}{100\%} \right)$$

To convert back to percentages, just multiply the calculated ratio by 100%:

Percentage Power =
$$100\% \times \log^{-1} \left(\frac{dB}{10} \right)$$

Percentage Voltage =
$$100\% \times \log^{-1} \left(\frac{dB}{20} \right)$$

Here's a practical application for converting dB to percentages and vice versa. Suppose you are using an antenna feed line with a signal loss of 1 dB. You can calculate the amount of transmitter power that's actually reaching your antenna and how much is lost in the feed line.

Percentage Power =
$$100\% \times \log^{-1} \left(\frac{-1}{10} \right) = 100\% \times \log^{-1} (-0.1) = 79.4\%$$

So 79.4% of your power is reaching the antenna and 20.6% is lost in the feed line.

Example 3: A power ratio of $20\% = 10 \log (20\% / 100\%) = 10 \log (0.2) = -7 dB$

Example 4: A voltage ratio of $150\% = 20 \log (150\% / 100\%) = 20 \log (1.5) = 3.52 dB$

Example 5: -3 dB represents a percentage power = $100\% \times \log^{-1}(-3/10) = 50\%$

Example 6: 4 dB represents a percentage voltage = $100\% \times \log_{-1} (4/20) = 158\%$

3.3 Using the *Windows* Scientific Calculator

If you have a suitable scientific calculator, it should easily do your calculations. Not all have an ANTILOG button, but if not, they will likely have a button that says X^Y, which can be used as above. If

Calculator X **SCIENTIFIC** J DEG HYP F-E M+ M-MS x^2 x^y sin cos tan 10^x log Exp Mod 1 CF C **⟨**× π 7 9 × 5 n! 4 6 2 3 + + 1 0 (

you don't have a handheld calculator, you can use the Calculator accessory in the Microsoft *Windows*

Figure 1 — Screen shot of the *Windows* 10 scientific calculator ready to find the power loss of 2 dB.

Table 2 Common dB Values For Ratios of Power and Voltage

1/2/1/1

۸D

P2/P1	иБ	V∠/V I	uБ
0.1	-10	0.1	-20
0.25	-6	0.25	-12
0.5	-3	0.5	-6
1	0	0.707	-3
2	3	1	0
4	6	1.414	3
10	10	2	6
		4	12
		10	20

operating system For *Windows 7* and earlier versions, click START, then ALL PROGRAMS, then ACCESSORIES. For *Windows 10*, click START, then look in the menu for CALCULATOR.

On first opening the calculator, you may find a four-function Standard calculator. To change to a Scientific calculator in the *Windows 7* and earlier versions, click on VIEW, then SCIENTIFIC to get the one you want. In the *Windows 10* version, click the MENU icon and select SCIENTIFIC. The *Windows 10* version is shown in **Figure 1**.

Let's say you have a mismatched coax cable with a loss of 2 dB. You may want to know how much of the 100 W generated by your transmitter actually reaches your antenna. Remember, a 2 dB loss is a "gain" of -2 dB. Using your *Windows Calculator*:

- Press 2 on your keyboard, or click 2 on the calculator keypad.
- Click on the ± key, then ÷, 1, 0, and =. The display should show -0.2, as in Figure 1.
- Click on 10^{X} to raise 10 to the power of -0.2.

The display should show 0.6309573444 (a number with many digits), which is about 0.63. That is the fraction of power left after a 2 dB loss. That means of the 100 W transmitted, the antenna sees 63 W and 37 W is heating the feed line.

3.4 Decibel Calculation with Special References

While the general use of decibels is as a ratio of input to output, they are also used to represent particular power or voltage levels by defining the base power or voltage at a particular level. In this case, the dB units will have a suffix indicating the reference. For example, to indicate power compared to 1 W, we would use the symbol dBW. For example, a signal level of 13 dBW would indicate power of 13 dB greater than 1 W which is 200 W. Other common references are shown below:

dBd — decibels of gain with respect to a dipole antenna in its preferred direction

dBi — decibels of gain with respect to that of an ideal isotropic antenna

dBmV — voltage level in decibels compared to a millivolt dB μ V — voltage level in decibels compared to a microvolt dBm (dBmW) — power level in decibels compared to a milliwatt dB μ W — power level in decibels compared to a microwatt

For example, if we had an amplifier with a gain of 30 dB and applied an input signal of 10 dBm, we would have an output power of 40 dBm or 10 dBW, which is 10 W. Note that the amplifier gain is in dB, a unitless ratio, while the input and output levels are in dBm or dBW, representing particular powers.

4 Coordinate Systems

4.1 Rectangular and Polar Coordinates

Graphs are drawings of what equations describe with symbols — they're both saying the same thing. The way in which mathematical quantities are positioned on the graph is called the *coordinate system*. *Coordinate* is another name for the numeric scale that divides the graph into regular units. The location of every point on the graph is described by a set of *coordinates*.

The two most common coordinate systems used in radio are the *rectangular-coordinate* system shown in **Figure 2A** (sometimes called *Cartesian coordinates*) and the *polar-coordinate* system shown in Figure 2B.

The line that runs horizontally through the center of a rectangular coordinate graph is called the *X axis*. The line that runs vertically through the center of the graph is called the *Y axis*. Every point on a rectangular coordinate graph has two coordinates that identify its location, X and Y, also written as (X,Y). Every different pair of coordinate values describes a different point on the graph. The point at which the two axes cross — where the numeric values on both axes are zero — is called the *origin*, written as (0,0).

In Figure 2A, the point with coordinates of (3,5) is located 3 units to the right of the origin along the X axis and 5 units above the origin along the Y axis. Another point at (-2,-4) is found 2 units to the left of the origin along the X axis and 4 units below the origin along the Y axis.

In the polar-coordinate system, points on the graph are also described by a pair of numeric values called *polar coordinates*. In this case we use a length, or *radius*, measured from the origin, and an *angle* from 0° to 360° measured counterclockwise from the 0° line as shown in Figure 2B. The symbol r is used for the radius and θ for the angle. A number in polar coordinates is written $r \angle \theta$. So the two points described in the last paragraph could also be written as $(5.83, \angle 59.0^{\circ})$ and $(4.5, \angle 243.4^{\circ})$ and are drawn as polar coordinates in Figure 2B. Remember that unlike maps, the 0° direction is always to the *right* and not to the top. In mathematics, 0° is not north!

A negative angle essentially means, "turn the other way." With positive angles measured counterclockwise from the 0° axis, the polar coordinates of the point at lower left in Figure 2B would be $(4.5, \angle -116.6^{\circ})$. When you encounter a negative value for the angle, it means to measure the angle clockwise from 0° . For example, -270° is equivalent to 90° ; -90° is equivalent to 270° ; 0° and -360° are equivalent; and $+180^{\circ}$ and -180° are equivalent. An angle can also be specified in *radians* (1 radian = $360 / 2\pi = 57.3$ degrees) but all angles are in degrees in the *Handbook* unless stated otherwise.

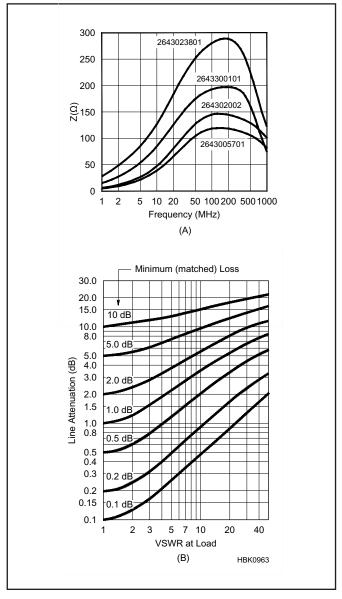

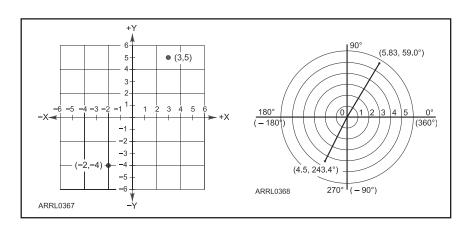

Figure 3 — A semi-log graph (A) with a logarithmic horizontal axis and linear vertical axis. A log-log graph (B) with both horizontal and vertical axes have a logarithmic scale.

Figure 2 — Rectangular-coordinate graphs (A) use a pair of axes at right angles to each other, each calibrated in numeric units. Any point on the resulting grid and be expressed in terms of its horizontal (X) and vertical (Y) values, called coordinates. Polar-coordinate graphs (B) use a radius from the origin and an angle from the 0° axis to specify the location of a point. Thus, the location of any point can be specified in terms of a radius (r) and an angle (θ) .

SEMI-LOG AND LOG-LOG GRAPHS

Many elements of radio and electronics have at least one aspect that behaves logarithmically or exponentially. Graphing that behavior is difficult or unclear if a linear scale is used since the ranges of the variables are usually quite large. A linear scale tends to compress all the "interesting" behavior into a corner or along one edge of the chart. In order to better view the behavior, the semi-log and log-log charts were created. (See **Figure 3**.)

The semi-log chart has one axis in which the scale is divided logarithmically. Figure 3A shows the relationship between impedance

of ferrite beads on the vertical (Y) axis and frequency on the horizontal (X) axis. This allows the impedance to be plotted over the entire frequency range of 1 MHz to 1 GHz. If a linear scale was used for frequency, the curve would be quite flat and it would be difficult to see the peak. When one variable has a limited range (impedance in this case) and the other has a wide range, a semi-log graph is often best.

The log-log chart in Figure 3B shows the relationship between two logarithmic variables — line loss and frequency. Both variables have a very wide range. The use of the log scale for line loss in dB greatly

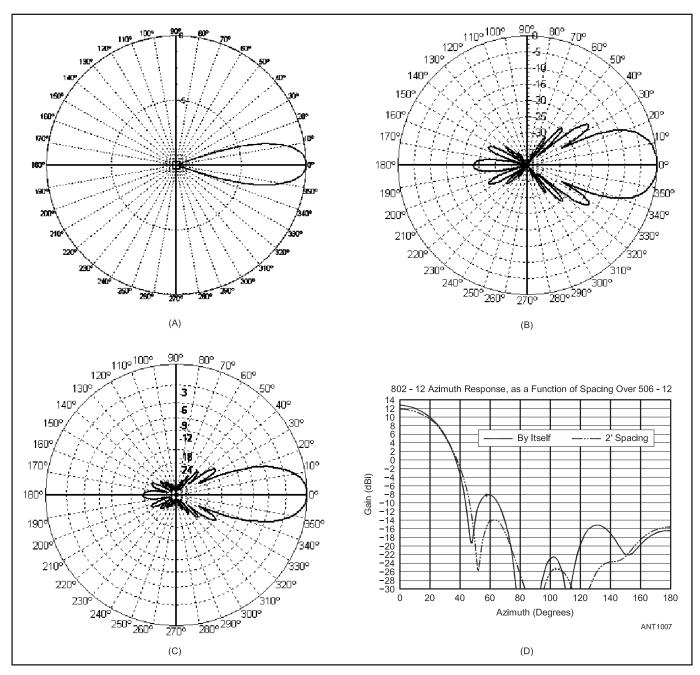

Figure 4 — Radiation pattern plots for a high-gain Yagi antenna on different grid coordinate systems. At A, the pattern on a linear-power dB grid. Notice how details of side lobe structure are lost with this grid. At B, the same pattern on a grid with constant 5 dB circles. The side lobe level is exaggerated when this scale is employed. At C, the same pattern on the modified log grid used by ARRL. The side and rearward lobes are clearly visible on this grid. The concentric circles in all three grids are graduated in decibels referenced to 0 dB at the outer edge of the chart. The patterns look quite different, yet they all represent the same antenna response! D shows the rectangular azimuthal patterns of two VHF Yagi antennas. This example shows how a rectangular plot allows easier comparison of antenna patterns away from the main lobe.

expands the area occupied by the line loss curves at low VSWR, which is of most interest. If the vertical scale was not logarithmic, the family of curves would be very compressed in the region of primary interest and difficult to read. When both variables have a very wide range, use a log-log graph.

4.2 Coordinates for Radiation Patterns

A number of different systems of coordinate scales or grids are in use for plotting antenna patterns. (Antenna radiation patterns are discussed in the **Antennas** chapter.) Antenna patterns published for amateur audiences are sometimes placed on rectangular grids, but more often they are shown using polar coordinate systems. Polar coordinate systems may be divided generally into three classes: *linear*, *logarithmic* and *modified logarithmic*.

A very important point to remember is that the shape of a pattern (its general appearance) is highly dependent on the grid system used for the plotting. This is exemplified in **Figure 4**, where the radiation pattern for a beam antenna is presented using three coordinate systems described below.

LINEAR COORDINATE SYSTEMS

The polar coordinate system in Figure 4A uses linear coordinates. The concentric circles are equally spaced, and are graduated from 0 to 10. Such a grid may be used to prepare a linear plot of the power contained in the signal. For ease of comparison, the equally spaced concentric circles have been replaced with appropriately placed circles representing the decibel response, referenced to 0 dB at the outer edge of the plot. In these plots the minor lobes are suppressed. Lobes with peaks more than 15 dB or so below the main lobe disappear completely because of their small size. This is a good way to

show the pattern of an array having high directivity and small minor lobes. Linear coordinate patterns are not common, however.

LOGARITHMIC COORDINATE SYSTEM

Another coordinate system used by antenna manufacturers is the logarithmic grid, where the concentric grid lines are spaced according to the logarithm of the voltage of the signal. If the logarithmically spaced concentric circles are replaced with appropriately placed circles representing the decibel response, the decibel circles are graduated linearly. In that sense, the logarithmic grid might be termed a linear-log grid, one having linear divisions calibrated in decibels.

This grid enhances the appearance of the minor lobes. If the intent is to show the radiation pattern of an array supposedly having an omnidirectional response, this grid enhances that appearance. An antenna having a difference of 8 or 10 dB in pattern response around the compass appears to be closer to omnidirectional on this grid than on any of the others. See Figure 4B.

ARRL LOG COORDINATE SYSTEM

The modified logarithmic grid used by the ARRL has a system of concentric grid lines spaced according to the logarithm of 0.89 times the value of the signal voltage. In this grid, minor lobes that are 30 and 40 dB down from the main lobe are distinguishable. Such lobes are of concern in VHF and UHF operation. The spacing between plotted points at 0 dB and -3 dB is significantly greater than the spacing between -20 and -23 dB, which in turn is significantly greater than the spacing between -50 and -53 dB.

For example, the scale distance covered by 0 to 3 dB is about $\frac{1}{10}$ of the radius of the chart. The scale distance for the next 3-dB increment (to -6 dB) is slightly less, 89% of the first, to be exact. The scale distance for the next 3-dB increment (to -9 dB) is again 89%

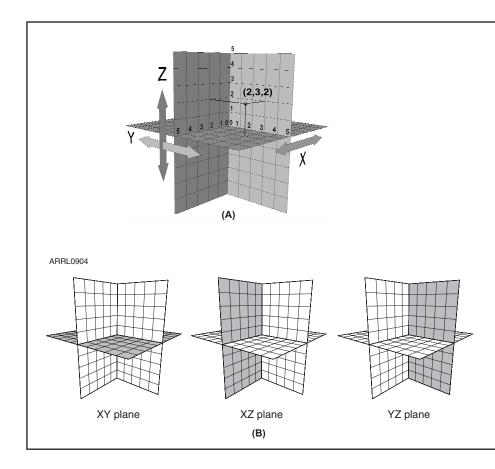

Figure 5 — In a three-dimensional rectangular coordinate system (A), a third axis, the Z axis, is added at right angles to both the X and Y axes. In X-Y-Z coordinates, the three coordinates can be used to specify a point's location anywhere in space. The set of axes has been oriented to show all three positive axes. Three rectangular coordinate planes (B). Each pair of axes creates a plane in which the coordinate for the third axis is zero. All points in the X-Y plane have a Z coordinate of zero, for example. The set of axes has been oriented to show all three positive axes.

of the second. The scale is thus constructed so that the inner-most two circles represent -36 and -48 dB and the chart center represents -100 dB.

The periodicity of spacing thus corresponds generally to the relative significance of such changes in antenna performance. Antenna pattern plots in ARRL publications are usually made on the modified-log grid similar to that shown in Figure 4C.

RECTANGULAR GRID

Antenna radiation patterns can also be plotted on rectangular coordinates with gain on the vertical axis in dB and angle on the horizontal axis as shown in Figure 4D. Multiple patterns in polar coordinates can be difficult to read, particularly close to the center of the plot. Using a rectangular grid makes it easier to evaluate low-level minor lobes and is especially useful when several antennas are being compared.

4.3 Three-Dimensional Coordinate Systems

RECTANGULAR (X-Y-Z)

Figure 5A adds a third axis, the *Z axis*, to the X and Y axes. This creates a three-dimensional system of coordinates in which any location is specified by three numbers instead of two. In Figure 5A, the indicated point's location is 2 units along the X axis, 3 units along the Y axis, and 2 units along the Z axis. The X and Y axis are usually assigned to be the "horizontal" plane and the Z axis to be "height" above the horizontal plane.

Each pair of axes defines a *plane* — an infinitely thin sheet that extends to infinity along both axes. The X-Y-Z coordinate system has three such planes as illustrated in Figure 5B. For all points in each of these planes, one coordinate is always zero: in the X-Y plane,

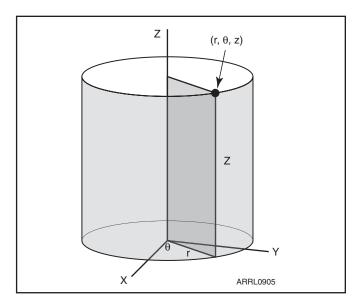

Figure 6 — Cylindrical coordinates. By adding a Z coordinate, a cylinder is created whose center is at the origin with a radius of r and a height of z. A point's location in cylindrical coordinates is specified as (r, θ, z) .

the Z coordinate is zero, in the Y-Z plane, the X coordinate is zero, and in the X-Z plane, the Y coordinate is zero.

CYLINDRICAL (R, θ, Z)

As when specifying the location of points in the X-Y plane using polar coordinates, r is used for the radius. The Greek letter theta (θ) is used for the angle which is measured counterclockwise from the 0° line as shown. A number in polar coordinates is written $r \angle \theta$.

If the Z axis is added, a cylinder is created with a radius of r and a height of z. The angle θ defines a vertical line along the cylinder. The type of coordinate system in **Figure 6** is called *cylindrical coordinates* and a point's location is given as (r, θ, z) .

SPHERICAL (R, θ , ϕ) OR AZIMUTH-ELEVATION

Instead of using Z as a third coordinate, another useful method of locating a point is with a second angle as shown in **Figure 7**, creating *spherical coordinates*. The angle in the X-Y plane (θ) is called the *azimuth* angle and it corresponds to direction in the horizontal plane. The second angle, ϕ , is measured between the horizontal plane and the point and is called the *elevation* angle.

When used in the real world, elevation is measured from the horizontal plane to the point, so a point on the ground has an elevation of 0° and a point directly overhead at the *zenith* has an elevation of 90° .

In spherical coordinates, the position of a point is given as (r, θ) , θ). Spherical coordinates are the standard used by antenna modelers to describe antenna radiation patterns and the coordinates (r, azimuth, and elevation) are used.

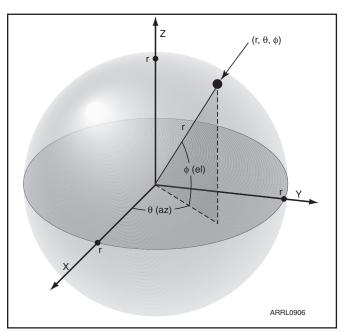

Figure 7 — Spherical coordinates. Each point lies on the surface of a sphere with its center at the origin. The position of the point is given as the radius of the sphere, r, and the azimuth (θ) and elevation (ϕ) angles.

5 Exponential Equations

An exponential equation is one in which the variable is an exponent of a constant, another variable, or some kind of mathematical formula (expression). By far, the most common exponential equations in electronics and radio are based on the number e, or Euler's number, which has a value of 2.71828... Similarly to the transcendental number π (3.14159...), the value of e is irrational and has an infinite number of digits. It is the base of the *natural logarithm*, which in written \log_e or \ln

The most common use of e in electronics is in calculating the charging and discharging time constants of capacitor and inductor circuits. Two typical equations that form the basis of timing calculations are:

Charging: $V(t) = E(1 - e^{-t/\tau})$

Discharging: $V(t) = E(e^{-t/\tau})$

where V(t) is the voltage across a capacitor changing with time, E represents the final dc voltage (charging) or the initial dc voltage (discharging) across the capacitor, τ (tau) is the circuit's *time constant* which is determined by the circuit component values, and t is time. (These circuits are discussed in more detail in the chapter on **Electrical Fundamentals**. Similar equations apply to current in an inductor.)

The capacitor charging and discharging voltages are show in **Figure 8**, where the time axis is shown in terms of τ and the vertical axis is expressed as a percentage of the applied voltage. These graphs are representative of all simple RC and RL circuits.

These equations can be solved fairly easily with a calculator that is able to work with natural logarithms (it will have a key labeled LN or LN X). You can also calculate the value for $e^{-t/\tau}$ as the inverse natural log of $-t/\tau$, written as ln^{-1} ($-t/\tau$).

As shown on the graphs of Figure 8, it is common practice to think of charge or discharge time in terms of multiples of the circuit's time constant. If we select times of zero (starting time), one time constant (1τ) , two time constants (2τ) , and so on, then the exponential term in the equations simplifies to e^0 , e^{-1} , e^{-2} , e^{-3} and so forth. Then we can solve the equations for those values of time.

Using the example of a capacitor being charged, assume that a dc voltage E = 100 V is applied so that the voltages will have the same

value as a percentage of E.

After a time equal to five time constants has passed, the capacitor is charged to 99.3% of the applied voltage. This is fully charged for all practical purposes.

The equation used to calculate the capacitor voltage while it is discharging is slightly different from the one for charging. The resulting curve, though, is similar to the charging curve. For values of time equal to multiples of the circuit time constant:

```
t = 0,
                                 so V(0)
                                                                     100%
t = 1\tau
           e^{-1}
                       0.368.
                                so V(1τ)
                                                  36.8 V.
                                                                     36.8%
                =
                                             =
                                                             or
           e-2
t = 2\tau
                       0.135,
                                 so V(2τ)
                                                  13.5 V,
                                                                     13.5%
           e-3
t = 3\tau
                =
                       0.050,
                                 so V(3τ)
                                                 5 V,
                                                                     5%
                                             =
                                                             or
           e^{-4}
                                                                     1.8%
t = 4t
                 =
                       0.018,
                                 so V(4τ)
                                              =
                                                  1.8 V
                                                             or
t = 5\tau
                       0.007,
                                 so V(5τ)
                                                  0.7 V,
                                                                    0.7%
```

Here we see that after a time equal to five time constants has passed, the capacitor has discharged to less than 1% of its initial value. This is fully discharged for all practical purposes.

Another way to think of these results is that the discharge values are the complements of the charging values. Subtract either set of percentages from 100 and you will get the other set. You may also notice another relationship between the discharging values. If you take 36.8% (0.368) as the value for one time constant, then the discharged value is $0.368^2 = 0.135$ after two time constants, $0.368^3 = 0.05$ after three time constants, $0.368^4 = 0.018$ after four time constants and $0.368^5 = 0.007$ after five time constants. You can change these values to percentages, or just remember that you have to multiply the decimal fraction times the applied voltage. If you subtract these decimal values from 1, you will get the values for the charging equation. In either case, by remembering the percentage 63.2% you can generate all of the other percentages without logarithms or exponentials!

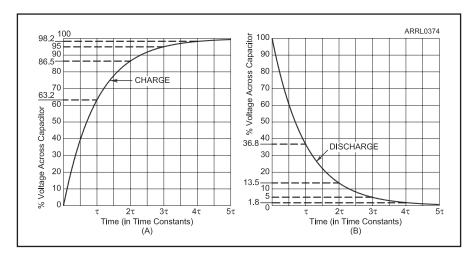

Figure 8 — The graph at A shows how the voltage across a capacitor rises with time when charged through a resistor (an RC circuit). Graph B shows how the voltage decreases with time as the capacitor is discharged through a resistor. The dashed lines represent voltage across the capacitor after 1, 2, 3, and 4 time constants (τ) have passed.

6 Complex Numbers

You will frequently encounter numbers that contain the square root of minus one (-1), represented by i in regular mathematics. To avoid confusion with current in electronics, the symbol j is used instead. Since there is no real number that when squared produces -1, any number that contains i or j is called an *imaginary number*. For example, 2j, 0.1j, 7j/4, and 457.6j are all imaginary numbers.

The number j has a number of interesting properties:

$$1/j = -j$$

$$j^2 = -1$$

$$j^3 = -j$$

$$j^4 = 1$$

$$j = 1 \angle 90^\circ$$

Multiplication by j can also represent a phase shift of $+90^{\circ}$.

Real and imaginary numbers can be combined by using addition or subtraction. Combining real and imaginary numbers creates a hybrid called a *complex number*, such as 1+j or 6-j7. (The convention in complex numbers is for j to be first in the imaginary part of the number.) These numbers come in very handy in radio, describing impedances, relationships between voltage and current, and many other phenomena.

If the complex number is broken up into its real and imaginary parts, those two numbers can also be used as coordinates on a graph using *complex coordinates*. This is a special type of rectangular-coordinate graph that is also referred to as the *complex plane*. By convention, the X axis coordinates represent the real number portion of the complex number and the Y axis represents the imaginary portion. For example, the complex number 6-j7 would have the same location as the point (6,-7) on a rectangular-coordinate graph. **Figure 9** shows the same points as Figure 2, but now they are representing the complex numbers 3+j5 and -2-j4, respectively.

6.1 Working With Complex Numbers

Complex numbers representing electrical quantities can be expressed in either rectangular form (a + jb) or polar form (r $D\theta$). Adding complex numbers is easiest in rectangular form:

$$(a+jb) + (c+jd) = (a+c) + j(b+d)$$

Multiplying and dividing complex numbers is easiest in polar form:

$$a \angle q_1 \times b \angle q_2 = (a \times b) (q_1 + q_2)$$

and

$$\frac{a\angle\theta_1}{b\angle\theta_2} = \left(\frac{a}{b}\right) \angle \left(\theta_1 - \theta_2\right)$$

Converting from one form to another is useful in some kinds of calculations. For example, to calculate the value of two complex impedances in parallel you use the formula

$$Z = \frac{Z_1 Z_2}{Z_1 + Z_2}$$

To calculate the numerator (Z_1Z_2) you would write the impedances in polar form. To calculate the denominator (Z_1+Z_2) you would write the impedances in rectangular form. So you need to be able to convert back and forth from one form to the other. There is a good explanation of this process, with examples, in the tutorials on complex numbers referenced in the Tutorial on Mathematics section at the end of this chapter.

Here is the short procedure you can save for reference:

To convert from rectangular (a + jb) to polar form $(r \angle \theta)$:

$$r = \sqrt{(a^2 + b^2)}$$

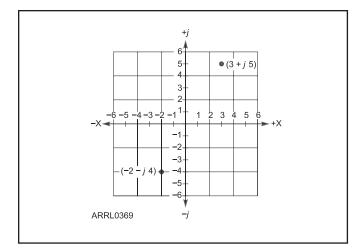

Figure 9 — The Y axis of a complex-coordinate graph represents the imaginary portion of complex numbers. This graph shows the same numbers as in Figure 1A, graphed as complex numbers.

$$\theta = \tan^{-1}\left(\frac{b}{a}\right)$$

To convert from polar to rectangular form:

 $a = r \cos \theta$

 $b = r \sin \theta$

Many calculators have polar-rectangular conversion functions built-in and they are worth learning how to use. Be sure that your calculator is set to the angle units you prefer, radians or degrees.

Example

Convert $3 \angle 30^{\circ}$ to rectangular form:

$$a = 3 \cos 30^{\circ} = 3 (0.866) = 2.6$$

$$b = 3 \sin 30^{\circ} = 3 (0.5) = 1.5$$

$$3\angle 30^{\circ} = 2.6 + i1.5$$

Example

Convert 0.8 + i0.6 to polar form:

$$r = \sqrt{(0.8^2 + 0.6^2)} = 1$$

$$\theta = \tan^{-1}\left(\frac{0.6}{0.8}\right) = 36.8^{\circ}$$

$$0.8 + j0.6 = 1 \angle 36.8^{\circ}$$

It is also common to calculate the reciprocal of a complex number. This is easiest to do in polar form. The reciprocal of a complex number $r \angle \theta$ is $(1/r) \angle -\theta$. When taking the reciprocal of an angle, the sign is changed from positive to negative or vice versa.

Many calculators have polar-rectangular conversion functions built-in and they are worth learning how to use. Be sure that your calculator is set to the correct units for angles, radians or degrees.

7 Vectors and Phasors

Vectors

A vector is a quantity that has both a magnitude and a direction. In radio, the most commonly encountered vectors are used to describe impedance as a complex number (described in the previous section) and an ac signal (see the Radio Fundamentals chapter's discussion of Sine Waves and Rotation). For basic vector concepts, see the excellent online tutorial about vectors at www.intmath.com/vectors/ vectors-intro.php.

Any quantity that can be represented as a complex number, can be drawn as a vector. This is described in the Electrical Fundamentals chapter's section on Impedance. The mathematical rules for working with vectors that have two coordinates (like impedance) are the same as for complex numbers in the previous sections. A vector is usually drawn as an arrow starting at the origin of the X-Y plane. To distinguish vectors from ordinary quantities, they are usually written in **bold** font and often with a small half-arrow above them. For example, V or Z are a voltage vector and an impedance vector, respectively.

Vectors can be drawn anywhere on the X-Y plane but in radio applications, they are usually shown as an arrow beginning at the origin (0,0). The arrow's length is the magnitude of the vector and the arrowhead shows the direction of the vector. For example, in the same section of the *Handbook*, Figure 2.66 (2018 edition) shows the impedance $50 + i 100 \Omega$ as a vector.

AC signals can also be drawn as vectors. In this case, the magnitude of the vector is the signal's voltage (or current) and you can use peak or RMS values. (If more than one vector is being combined, the peak or RMS convention must be the same for all of them.) The direction of the vector represents phase. If all of the signals and vectors have the same frequency, the angle between the vectors represents the phase angle between the signals.

Adding vectors together graphically is very simple, as shown in **Figure 10**, by arranging the vectors "head to tail". Start by imagining all of the vectors as starting at the origin. Figure 10 shows two ac voltages, V_A and V_B, both with the same frequency, being added

together to create V_{C} . Begin with V_{A} and add V_{B} to it by "moving" it (without changing its direction) so that the arrow for V_B starts at the arrowhead of V_A. (You could also move $V_{\mbox{\scriptsize A}}$ to start at the end of $V_{\mbox{\scriptsize B}}.$ The order doesn't matter.) The resulting vector, V_C, is drawn from the head of the first vector (at the origin) to the tail of the last vector.

Subtraction works similarly. Turn the vector to be subtracted by 180° and add as before. This is the same as subtracting an ordinary number by multiplying it by -1 and adding. Figure 10B shows what happens when V_C is created by subtracting V_B from V_A.

When impedances are combined in series and parallel circuits, their vectors are multiplied and divided according to the rules for complex numbers above. Examples of how to work with impedances and admittances in this way are given in the Handbook. The Extra Class License Manual also includes a number of examples since questions of that sort are on the exam as of 2017.

More complicated vector combinations are involved in performing modulation, mixing signals, doing transmission line calculations, and so forth. Should you need to "do the math" for these functions, you'll be well beyond what this supplement can tell you!

Phasor Notation

When working with complex numbers, using polar notation can be much more convenient for multiplying and dividing. This is also true for vectors, where is it called *phasor notation*. For example, an impedance of $50 + i 100 \Omega$ would be written $112 \angle 63.4^{\circ}$.

Multiplying phasor A by phasor B requires you to multiply the magnitudes and add the angles:

$$V_A \angle \phi_A \times V_B \angle \phi_B = V_A V_B \angle (\phi_A + \phi_B)$$

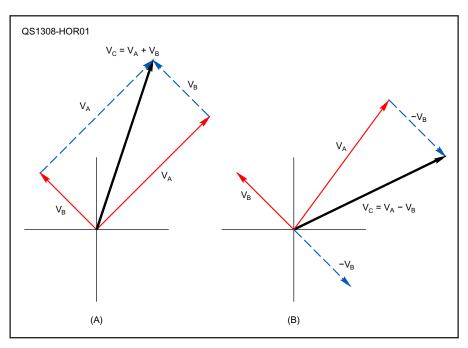

Figure 10 — Adding and subtracting vectors. Representing voltages here, vectors can be added together (A) by placing them "head to tail" in any order. (B) shows how subtraction is performed by reversing the vector to be subtracting and then adding it as in (A).

Similarly, to divide phasors, divide the magnitudes and subtract one angle from the other.

$$V_A \angle \phi_A \div V_B \angle \phi_B = (V_A / V_B) \angle (\phi_A - \phi_B)$$

Remember that to use phasor notation this way requires both signals to have exactly the same frequency so that ϕ_A and ϕ_B are constant. If that isn't true, these formulas cannot be used. To add phasors requires that they be converted into rectangular complex numbers (a+jb) first.

Phasor Diagrams

When dealing with RF signals and circuitry, it's often true that the frequency of all signals in use is the same. Think of an RC low-pass filter, for example: the input signal $V_{IN} \sin{(\omega t+0)}$ and output signal $V_{OUT} \sin{(\omega t+\phi)}$ have the same frequency $(\omega=2\pi f)$, even though their amplitudes are different. The filter's attenuation is given by the ratio of $|V_{OUT}|/|V_{IN}|$ and they are offset in phase by ϕ .

If the same frequency can be assumed for all signals, phasor notation can used to describe each signal as $|V| \angle \phi$ where ϕ is just the phase angle between a signal and some reference signal or phase. The input signal to a circuit is usually the reference for measuring phase differences. The form $|V| \angle \phi$ is a phasor and when drawn on an X-Y plane as vectors, the result is a *phasor diagram*. **Figure 11** is a phasor diagram showing a filter's input and output signals as phasors. The difference in length of the phasors shows the filter's attenuation and the angle between them shows the phase shift through the filter.

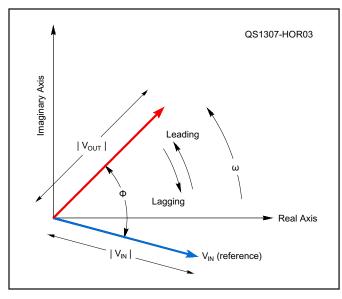

Figure 11 — A phasor diagram showing a filter's input signal $|V_{IN}| \angle 0^{\circ}$ acting as the phase reference (thus the angle of 0°) and the filter's output signal $|V_{OUT}| \angle \phi$. The frequency is the same for both signals.

8 Boolean Algebra

The fundamental principle of digital electronics is that a signal can have only a finite number of discrete values or *states*. In *binary* digital systems signals may have two states, represented in *base-2 arithmetic* by the numerals 0 and 1. The binary states described as 0 and 1 may represent an OFF and ON condition or as space and mark in a communications transmission such as CW or RTTY. Since our interest in digital signals is primarily circuit-oriented, we will refer to logic circuit elements in this section.

The simplest digital devices are switches and relays. Electronic digital systems, however, are created using *digital ICs* — integrated circuits that generate, detect or in some way process digital signals. Whether switches or microprocessors, though, all digital systems use common mathematical principles known as *binary logic*. We'll start with the rules for combining different digital signals, called *combinational logic*. These rules are derived from the mathematics of binary numbers, called *Boolean algebra*, after its creator, George Boole.

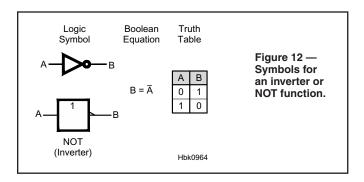

In binary digital logic circuits each combination of inputs results in a specific output or combination of outputs. Except during transitions of the input and output signals (called *switching transitions*), the state of the output is determined by the simultaneous state(s) of the input signal(s). A combinational logic function has one and only one output state corresponding to each combination of input states. The output of a combinational logic circuit is determined entirely by the information at the circuit's inputs.

The simplest Boolean functions are called *elements*. Combinational logic elements may perform arithmetic or logical operations. Regardless of their purpose, these operations are usually expressed in arithmetic terms. Digital circuits add, subtract, multiply, and divide but normally do it in binary form using two states that we represent with the numerals 0 and 1.

Binary digital circuit functions are represented by equations using Boolean algebra. The symbols and laws of Boolean algebra are somewhat different from those of ordinary algebra. The symbol for each logical function is shown here in the descriptions of the individual logical elements. The logical function of a particular element may be described by listing all possible combinations in input and output values in a *truth table*.

ONE-INPUT ELEMENTS

The *inverter* or NOT circuit (**Figure 12**) inverts a 1 at the input to produce a 0 at the output, and vice versa. NOT indicates inversion, negation or complementation. The Boolean algebra notation for the NOT function is a bar over the variable or expression, such as $B = \overline{A}$.

THE AND OPERATION

A *gate* is defined as a combinational logic element with two or more inputs and one output state that depends on the state of the inputs. Gates perform simple logical operations and can be combined to form complex switching functions. So as we talk about the logical operations used in Boolean algebra, you should keep in mind that each function is implemented by using a gate with the same name. For example, an AND gate implements the AND operation.

The AND operation results in a 1 only when all inputs or *operands* are 1. That is, if the inputs are called A and B, the output is 1 only if A and B are both 1. In Boolean notation, the logical operator AND is usually represented by a dot between the variables (•). The AND function may also be signified by no space between the variables. Both forms are shown in **Figure 13**, along with the schematic symbol for an AND gate.

THE OR OPERATION

The OR operation results in a 1 at the output if any or all inputs are 1. In Boolean notation, the + symbol is used to indicate the OR function. The OR gate shown in **Figure 14** is sometimes called an INCLUSIVE OR. In Boolean algebra notation, a + sign is used between the variables to represent the OR function. Study the truth table for the OR function in Figure 12. You should notice that the OR gate will have a 0 output only when all inputs are 0.

THE NAND OPERATION

The NAND operation means NOT AND. A NAND gate (**Figure 15**) is an AND gate with an inverted output. A NAND gate produces a 0 at its output only when all inputs are 1. In Boolean notation, NAND is usually represented by a dot between the variables and a bar over the combination, as shown in Figure 13.

THE NOR OPERATION

The NOR operation means NOT OR. A NOR gate (**Figure 16**) produces a 0 output if any or all of its inputs are 1. In Boolean notation, the variables have a + symbol between them and a bar over the entire expression to indicate the NOR function. When you study the truth table shown in Figure 16, you will notice that a NOR gate produces a 1 output only when all of the inputs are 0.

THE EXCLUSIVE NOR OPERATION

The EXCLUSIVE OR (XOR) operation (**Figure 17**) results in an output of 1 if only one of the inputs is 1, but if both inputs are 1 then the output is 0. The Boolean expression \oplus represents the EXCLUSIVE OR function. Inverting the XOR function results in the EXCLUSIVE NOR (XNOR) operation.

DE MORGAN'S THEOREMS

It is common to need to transform logical expressions from an expression based on the AND (•) function to one based on the OR (+) function. Although the functions were known much earlier, De Morgan expressed them in the language of modern logic in the 19th century. By repeatedly applying these rules, even complex logic equations can be transformed.

$$\overline{\mathbf{A} \cdot \mathbf{B}} = \overline{\mathbf{A}} + \overline{\mathbf{B}}$$

and

$$\overline{A+B} = \overline{A} \cdot \overline{B}$$

9 Tutorials on Mathematics

The following web links are a compilation of online resources organized by topic. Many of the tutorials listed below are part of the Interactive Mathematics website (www.intmath.com), a free, online system of tutorials. The system begins with basic number concepts and progresses all the way through introductory calculus. The lessons referenced here are those of most use to a student of radio electronics.

9.1 Basic Numbers & Formulas

Order of Operations — www.intmath.com/Numbers/3_Order-ofoperations.php

Powers, Roots, and Radicals — www.intmath.com/Numbers/4_ Powers-roots-radicals.php

Scientific Notation —www.intmath.com/numbers/6-scientificnotation.php

Ratios and Proportions — www.intmath.com/Numbers/7_Ratioproportion.php

Geometric Formulas — www.equationsheet.com/sheets/ Equations-4.html

Radio Math Cheat Sheet

Here are many formulas and constants that are frequently used in Amateur Radio. You can save this on your smartphone or tablet or print it out and keep it in your toolbox or on the bench. No guessing required!

CONSTANTS

e = 2.71828; 1/e = 0.36788 $\pi = 3.14159$; $2\pi = 6.28318$; $4\pi = 12.5664$; $\pi/2 = 1.5708$; $\pi/4 = 0.785398$

 $\log_{10} = 2.303 \text{ x ln (or log}_e); \ln = \log_{10} / 2.303$

Time constants — charging

 $\tau = 1/e = 0.632$; $2\tau = 0.865$; $3\tau = -0.95$; $4\tau = 0.982$; $5\tau = 0.993$

Time constants — discharging

 $\tau = 1 = 1/e = 0.368$; $2\tau = 0.135$; $3\tau = 0.05$; $4\tau = 0.018$; $5\tau = 0.007$

TABLE OF CONVERSION FACTORS FOR SINUSOIDAL AC VOLTAGE OR CURRENT

Conversion Factors for Sinusoidal AC Voltage or Current

From Peak	<i>To</i> Peak-to-Peak	Multiply By 2
Peak-to-Peak	Peak	0.5
Peak	RMS	$1/\sqrt{2}$ or 0.707
RMS	Peak	$\sqrt{2}$ or 1.414
Peak-to-Peak	RMS	$1/(2 \times \sqrt{2})$ or 0.35355
RMS	Peak-to-Peak	$2 \times \sqrt{2}$ or 2.828
Peak	Average	2 / π or 0.6366
Average	Peak	π / 2 or 1.5708
RMS	Average	$(2 \times \sqrt{2})$ / π or 0.90
Average	RMS	$\pi / (2 \times \sqrt{2})$ or 1.11

Note: These conversion factors apply only to continuous pure sine waves.

Ohm's Law and Power Circle

During the first semester of my Electrical Power Technology program, one of the first challenges issued by our dedicated instructor — Roger Crerie — to his new freshman students was to identify and develop 12 equations or formulas that could be used to determine voltage, current, resistance and power. Ohm's Law is expressed as

R = E / I and it provided three of these equation forms while the basic equation relating power to current and voltage $(P = I \times E)$ accounted for another three. With six known equations, it was just a matter of applying mathematical substitution for his students to develop the remaining six. Together, these 12 equations compose the circle or wheel of voltage (E), current (I), resistance (R) and power (P)shown in Figure A. Just as Roger's previous students had learned at the

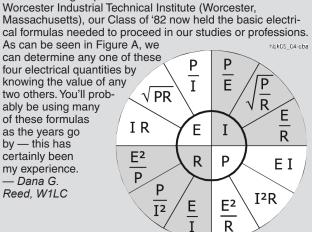

Figure A — Electrical formulas

REACTANCE

$$X_C = \frac{1}{2\pi fC}$$
 and $X_L = 2\pi fL$

POLAR-RECTANGULAR CONVERSION

To convert from rectangular (a + jb) to polar form $(r \angle \theta)$:

$$r = \sqrt{(a^2 + b^2)}$$
 and $\theta = tan^{-1} \left(\frac{b}{a}\right)$

To convert from polar to rectangular form: $a = r \cos \theta$ and $b = r \sin \theta$

DECIBELS

$$\begin{split} dB &= 10 \ log \ (P/\ P_{REF}) = 20 \ log \ (V\ /\ V_{REF}) \\ Power \ ratio &= log^{-1} \ (dB/10) \ and \ Voltage \ ratio = log^{-1} \ (dB/20) \end{split}$$

 $dB = 10 \log (percentage of power / 100) = 20 \log (percentage of power / 100)$ voltage / 100)

Percentage of power = $100\% \times \log^{-1} (dB/10)$

Percentage of voltage = $100\% \times \log^{-1} (dB/20)$

dBm: $P_{REF} = 1 \text{ mW}$; dBW: $P_{REF} = 1 \text{ W}$; dB μ W: $P_{REF} = 1 \mu$ W

dBV: $V_{REF} = 1 \text{ V}$; $dB\mu V$: $V_{REF} = 1 \mu V$

dBd = dBi - 2.15 and dBi = dBd + 2.15

 $1 \mu W = -30 \text{ dBm}$; 1 mW = 0 dBm; 1 W = 30 dBm

100 W = 50 dBm; 1 kW = 60 dBm

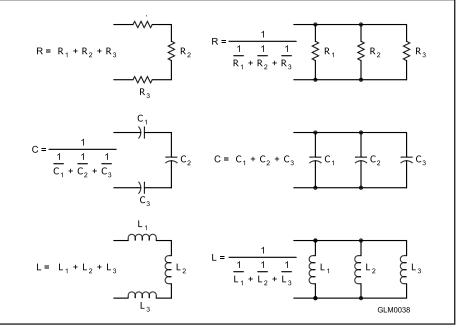

Common dB Values For Ratios of Power and Voltage

P2/P1	dB	V2/V1	dB
0.1	-10	0.1	-20
0.25	-6	0.25	-12
0.5	-3	0.5	-6
1	0	0.707	-3
2	3	1	0
4	6	1.414	3
10	10	2	6
		4	12
		10	20

PARALLEL AND SERIES COMPONENTS

How components in series and parallel are combined into a single equivalent value. For two resistors or inductors in parallel or for two capacitors in series use the simplified formula

Equivalent value
$$= \frac{Value 1 \times Value 2}{Value 1 + Value 2}$$

PEAK ENVELOPE POWER

$$PEP = \frac{\left[\frac{0.707 \times V_{Pk-Pk}^{2}}{2}\right]}{R_{LOAD}} = \frac{V_{RMS}^{2}}{R_{LOAD}}$$

FREQUENCY-WAVELENGTH CONVERSION

Frequency (in Hz) = 3×10^8 / Wavelength (in m)

Wavelength (in m) = 3×10^8 / Frequency (in Hz)

Frequency (in MHz) = 300 / Wavelength (in m)

Wavelength (in m) = 300 / Frequency (in MHz)

Half-wavelength in free space (in feet) = 492 / Frequency (in

Quarter-wavelength in free space (in feet) = 246 / Frequency (in

MHz)

LENGTH CONVERSION

Multiply meters by 3.28 to get feet Multiply meters by 39.4 to get inches Multiply meters by 1.09 to get yards Multiply yards by 0.914 to get meters Multiply feet by 0.305 to get meters Multiply inches by 2.54 to get centimeters Multiply feet by 30.5 to get centimeters Multiply centimeters by 0.0328 to get feet Multiply centimeters by 0.394 to get inches

TRIGONOMETRY AND ANGLES

1 radian (rad) = 57.3 degrees; 2π radians in a circle 1 degree = 0.0174 radians; 360 degrees in a circle $45^{\circ} = \pi/4 \text{ rad}$; $90^{\circ} = \pi/2 \text{ rad}$; $180^{\circ} = -180^{\circ} = \pi \text{ rad}$

 $270^{\circ} = -90^{\circ} = 3/\pi/2 \text{ rad} = -\pi/2 \text{ rad}$

1 revolution = 360° ; 2 rev = 720° ; 3 rev = 1080°

Sin $(\theta) = -\sin(-\theta) = \cos(\theta - 90^\circ)$ or $\cos(\theta - \pi/2 \text{ rad})$

Cos (θ) = cos $(-\theta)$ = sin $(\theta + 90^\circ)$ or sin $(\theta + \pi/2 \text{ rad})$

 $Sin (90^\circ) = sin (\pi/2 \text{ rad}) = cos (0) = 1$

 $\sin (45^\circ) = \sin (\pi/4 \text{ rad}) = \cos (45^\circ) = \cos (\pi/4 \text{ rad}) = 0.707$

 $Sin (30^\circ) = cos (60^\circ) = 0.5$

Sin (0) = $\cos (90^\circ) = \cos (\pi/2 \text{ rad}) = 1$

Sin (180°) = sin $(\pi \text{ rad})$ = 0; cos (180°) = cos $(\pi \text{ rad})$ = -1

 $\sin(270^\circ) = \sin(3\pi/2 \text{ rad}) = -1; \cos(270^\circ) = \cos(3\pi/2 \text{ rad}) = 0$

 $Tan(\theta) = sin(\theta) / cos(\theta) = height of structure / distance to struc$ ture base

Height of a structure = distance to base of structure \times tan (angle to top of structure)

Length of a guy wire =

 $\sqrt{\text{(distance to guy point)}^2 + \text{(height of guy attachment)}^2}$

Index

Editor's Note: Except for commonly used phrases and abbreviations, topics are indexed by their noun names. Many topics are also cross-indexed.

The letters "ff" after a page number indicate coverage of the indexed topic on succeeding pages.

A separate Project Index and Author Index follow the main index.

IEC identification and marking:		RF power transistors (MOSFET)	
Metalized film:		Specifications:	22.28ff
Non-inductive:	5.4	RF probe:	
Package dimensions:	22.3	RF sampler:	
Parasitic inductance:		RF sniffer:	
Parasitic inductance model:		RF transformers:	
Power:		Air-core resonant:	
Precision: 4.2		Binocular core:	
Pull-up:		Broadband ferrite:	
Resistor pack:		RF voltmeter:	
Series and parallel:		RFI (see RF interference)	
Standard values:		Right-hand rule:	2.19
Temperature coefficient (tempco):		Ringing (filter):	
Thick-film power:		Ripple:	
Thin-film resistor:		Bandwidth (filter):	
Types of resistors:		Filter:	
Wire-wound:		Frequency:	7.13
Resolution:		Voltage:	
Resolution bandwidth (RBW):		Rise (fall) time:	
Resonance:		Rise and fall time	
Of ferrite cores and chokes:	,	Keying:	25.37
Resonant circuits:		RJ connector:	
Antiresonance:		RL time constant (τ) :	
Bandwidth:		Robotics:	
Circulating current:		Construction:	
Impedance transformation:		Data platform:	
Parallel:		Subsystems:	
Parallel, loaded Q:		Rocketry, amateur:	
Parallel, use for impedance matching:		Construction:	
Resonant frequency:		Data platform:	
Selectivity:		Navigation:	
Series:		Subsystems:	
Series and parallel:		Roll-off:	
Series, unloaded Q:		Roll-off (filter):	
Resonant frequency:		Root-mean-square (RMS):	
Return loss (RL): 5.36,		Non-sinusoidal waveforms:	· ·
Converting between attenuation, reflection coefficient,	10.10, 20.4	Rope:	
and SWR:	22.61	Rowe, David VK5DGR:	
Return loss bridge (RLB):		RS-274X:	
Reverse Beacon Network:		RTL-SDR:	
Reverse bias:		RTTY	17.17
Reverse breakdown voltage:		Telemetry:	16 11
Reverse leakage current:		Run length encoding (RLE):	
RF ammeter: 2		Ruthroff transformer:

Glossary:		Assessing symptoms:	
Impedance of two-conductor twisted pair:		Battery hazards:	
Impedance transformation:		Circuit-level, analog:	
Impedance transformer:	20.22ff	Circuit-level, digital:	
Incident, forward, and reflected waves:	20.4	Completing repair:	
Ladder line:		Component level:	26.7ff
Length per dB of loss:		Connectors:	
Load:		DSP and SDR equipment:	
Lumped-constant:		General symptoms:	
Matched and mismatched:		High-voltage supplies:	
		Inspections:	
Measurements:		Newly constructed equipment:	
Microstrip:		Oscillators:	
Open-wire:		Power supplies:	
Parallel-conductor (twin-lead):	20.1	Professional repair:	26.22
PC board:		Radio frequency interference (RFI):	27.35ff
Phasing antennas:	20.14	Receivers:	26.25
Quarter-wave (Q) section:		Recommended equipment:	
Radiation cancellation in:		References:	
Radiation from:		Search engines:	
References:		Semiconductors:	
Selecting type of line:	20.6	Shack notebook:	
Specifications: Stripline: Stripl	10.26, 20.20	Signal tracing and injection:	26.1311
Stub placement:	20.10	Television interference (TVI):	
Stubs:		Transceiver:	
Synchronous transformer:		Transmit amplifier modules:	26.25
Termination:		Transmitters:	
Transformer:	17.30	Tube tester:	26.38
Twin-lead:		Vacuum tubes:	26.12
Velocity factor (VF):		Tube (see Vacuum tube)	24.20
VHF/UHF:		Tube tester:	
Washamasing		TubeCalculator software:	
Weatherproofing: Window line: W		Tubing, aluminum: Tuned circuit	21.31
Transmit-Receive (TR) switch:		Single-tuned circuit:	5 13
Transmitter	15.70	Tuning procedure	
Amplifier:	13.37	Amplifier, RF power:	17.14
Carrier and unwanted sideband suppression:		Tuning tools:	23.7, 23.25
CCS, ICAS, IMS rating:		Turn-around time, transmitter:	25.37
FCC regulations:		Tuska, Clarence:	
Heterodyne, upconverting:		Twelfth-wave transformer:	
Intermodulation distortion:		Twisted-pair speaker cable:	
Performance measurement:		Two-port network parameters:	
Phase noise:		Two-port parameters: Two-tone audio generator:	
SDR architecture:		Two-tone test:	
Speech processing:			11.27, 23.30
TR switch:		••	
Troubleshooting:		U	21.20
Two-tone test:		Uda (Yagi-Uda antenna):	
Transmitter power output (TPO):		Ufer ground:UHF (frequency range classification):	
Transverse electromagnetic mode (TEM):		UHF connector:	
Trap (antenna):		Ultimate attenuation (filter):	10.4
Traveling wave tube:		Ultraviolet radiation:	
Triac:		Unattended operation:	
	20.10, 20.11		

Underwriter Labs (UL):		Victim, RFI:

Unintentional emitters:		Vintage equipment:	1.17
Uninterruptible power supply (UPS):	28.13	Repair and restoration:	
Unipolar transistor (<i>see</i> Field-effect transistor) Units		Virtual height:	19.7
Systems of measurement:	25.1	VLF (frequency range classification): VOACAP:	
Units and conversion factors:	22.1	Vocoder:	
Unity-gain buffer:	22.36 4 47	AMBE:	· ·
Unmanned Aerial Vehicle (UAV):		DMR:	
Data platform:		Voice-operated transmit (VOX):	13.36
Navigation:		Volatile memory:	
Powering:		Volt-amp reactive (VAR):	
Subsystems:		Volt-ampere rating (transformer):	7.3
Upper sideband (USB):		Voltage	
USB battery charging:	7.39	Potential difference:	25.2
User interface (SDR):		Voltage (V, E):	
Control interface:	14.9	Voltage source:	
Panadapter display:		Volts (V):	
Waterfall display:	14.8	Voltage divider:	4.3
		Voltage multiplier:	
V		Full-wave voltage doubler:	1.1, 1.8
Vackar oscillator:	9.9	Half-wave voltage doubler:Voltage tripler and quadrupler:	
Vacuum tube:		Voltage probe:	25 22
Cathode:	17.4	Voltage reference IC:	A 52
Construction:		Voltage regulation:	7 13
Cooling methods:		Adjustable regulator:	7.19
Grid (control, screen, suppressor):		Dynamic and static regulation:	7.13
Grid dissipation:	17.15	Generator:	24.17
Nomenclature:		Three-terminal voltage regulator:	7.18
Operating parameters:	17.8ff	Voltage regulator IC:	4.52, 22.17
Pentode:		Specifications:	22.20
Plate (anode):		Voltage-controlled oscillator (VCO):	9.29, 9.35
Plate dissipation:Ratings:		Noise:	9.48
Screen dissipation:	17.15	Voltage-current converter:	4.51
Secondary emission:		Voltage-follower circuit:	4.47
Specifications:	22 34ff	Voltage-power conversion:	22.60
Tetrode:		Voltmeter	25.4
Thermionic emission:	17.4	Digital multimeter (DMM):	25.4
Triode:		Multiplier resistor:RF:	25.65
Troubleshooting:	26.12	Sensitivity, ohms-per-volt:	25.03
Varactor diode:	4.21	Vacuum-tube, VTVM:	25.3
Specifications:		Volume Meshing	
Variable crystal oscillator (VXO):	9.22	Finite difference time domain (FDTD):	6.16
Variable frequency oscillator (VFO):	9.5ff	Finite element method (FEM):	
Capacitor selection:		Transmission line method (TLM):	6.18
Construction:		Volunteer Consulting Engineer (VCE), ARRL:	
Inductor selection:		Volunteer Examiner (VE):	1.5
LC circuits:		VOM (volt-ohm-meter):	25.3
Shielding: Temperature compensation:		Von Neumann architecture:	8.15
Transistor selection:	9.13	VOX (see Voice-operated transmit)	
Varicode:		VSB, 8-VSB (see Vestigial sideband)	
Varistor:			
VCR (videotape cassette recorder) RFI:	27.42	W	
Vector network analyzer (VNA):		W1AW:	1.7
Low-frequency adapter:		W6ELProp:	
Vectors:	3.3, 11.14	Waterfall display:	
Complex impedance:	3.18	Watt (W):	
Velocity (radio wave):		Watt-hour (Wh):	2.9
Velocity factor (VF):		Wattmeter:	
Vertical amplifier:		Directional:	
Vertical antenna:		Reflectometer:	
Trap:		Wave cyclone:	19.26
Vertical interval signaling (VIS):	11.21	Waveforms	2.4
VFO (see Oscillator)	2.20	Complex:

Experimentation, Discovery, and Achievement.

The ARRL Handbook for Radio Communications is a complete reference and quide to radio technology principles and practices. Since 1926, *The ARRL Handbook* has been a trustworthy source of introductory, applied, and theoretical information. Now in its 96th edition, The Handbook continues to advance the pursuit of experimentation and innovation by radio amateurs and professionals. Each edition contains new and useful material to support Amateur Radio activity from the traditional short- and long-wave frequencies through microwaves!

Key Topics

- Radio electronics theory and principles
- Circuit design and equipment
- Radio signal transmission and propagation
 Construction practices
- Digital and analog modulation and protocols
- Antennas and transmission lines

Who reads The Handbook?

Amateur Radio operators, or "hams;" professional wireless communication engineers and system designers; electrical engineers; students and instructors of engineering, physics, and geoscience.

New Print and Downloadable Material—Always Updated!

- Simple SLA Float Charger project by John Boal, K9JEB
- Amateur Radio Data Platforms by Paul Verhage, KD4STH, and Bill Brown, WB8ELK
- The latest information on WSJT-X digital modes by the WSJT team
- Filter and circuit design software by Tonne Software and Jim Tonne, W4ENE—download only
- Low-Noise VHF and UHF Oscillators by Ulrich Rohde, N1UL, and Ajay Poddar, AC2KG
- Update on Solar Cycle 24 by Carl Luetzelschwab, K9LA
- Updated SSTV practices and technology by Larry Peterson, WA9TT—download only
- Designing dual-band loaded dipoles by David Birnbaum, K2LYV—download only
- Latest transceiver survey by Joel Hallas, W1ZR—download only

Plus, new component tables, reference articles, material characteristics, and guidelines for SDR design.

Download Included: eBook and Supplemental Content (included with print edition only) Download the fully searchable digital edition of the printed book, as well as expanded supplemental content, software, PC board templates, and other support files.

System Requirements: Windows 7, 8, or 10; Windows Vista or Windows XP, as well as Macintosh systems, using Adobe *Acrobat Reader* software. *Acrobat Reader* is a free download at www.adobe.com. PDF files are Linux readable. Other included software is Windows compatible only.

Companion Books Available

The ARRL Antenna Book for Radio Communications The ARRL Operating Manual for Radio Amateurs

About ARRL and the Amateur Radio Service

Amateur (Ham) Radio provides the broadest and most powerful wireless communications capability available to the private citizen anywhere in the world. The principles of this federally licensed radio service include public service, radio experimentation, training, and international goodwill. ARRL is the national membership association for Amateur Radio operators in the US. ARRL has books, software, online content, and other resources for licensing, operating, and lifelong learning.
